- *nested loop join*: The right relation is scanned once for every row found in the left relation. This strategy is easy to implement but can be very time consuming. (However, if the right relation can be scanned with an index scan, this can be a good strategy. It is possible to use values from the current row of the left relation as keys for the index scan of the right.)
- *merge join*: Each relation is sorted on the join attributes before the join starts. Then the two relations are scanned in parallel, and matching rows are combined to form join rows. This kind of join is attractive because each relation has to be scanned only once. The required sorting might be achieved either by an explicit sort step, or by scanning the relation in the proper order using an index on the join key.
- *hash join*: the right relation is first scanned and loaded into a hash table, using its join attributes as hash keys. Next the left relation is scanned and the appropriate values of every row found are used as hash keys to locate the matching rows in the table.

When the query involves more than two relations, the final result must be built up by a tree of join steps, each with two inputs. The planner examines different possible join sequences to find the cheapest one.

If the query uses fewer than `geqo_threshold` relations, a near-exhaustive search is conducted to find the best join sequence. The planner preferentially considers joins between any two relations for which there exists a corresponding join clause in the `WHERE` qualification (i.e., for which a restriction like `where rel1.attr1=rel2.attr2` exists). Join pairs with no join clause are considered only when there is no other choice, that is, a particular relation has no available join clauses to any other relation. All possible plans are generated for every join pair considered by the planner, and the one that is (estimated to be) the cheapest is chosen.

When `geqo_threshold` is exceeded, the join sequences considered are determined by heuristics, as described in [Chapter 60](#). Otherwise the process is the same.

The finished plan tree consists of sequential or index scans of the base relations, plus nested-loop, merge, or hash join nodes as needed, plus any auxiliary steps needed, such as sort nodes or aggregate-function calculation nodes. Most of these plan node types have the additional ability to do *selection* (discarding rows that do not meet a specified Boolean condition) and *projection* (computation of a derived column set based on given column values, that is, evaluation of scalar expressions where needed). One of the responsibilities of the planner is to attach selection conditions from the `WHERE` clause and computation of required output expressions to the most appropriate nodes of the plan tree.

## 53.6. Executor

The *executor* takes the plan created by the planner/optimizer and recursively processes it to extract the required set of rows. This is essentially a demand-pull pipeline mechanism. Each time a plan node is called, it must deliver one more row, or report that it is done delivering rows.

To provide a concrete example, assume that the top node is a `MergeJoin` node. Before any merge can be done two rows have to be fetched (one from each subplan). So the executor recursively calls itself to process the subplans (it starts with the subplan attached to `lefttree`). The new top node (the top node of the left subplan) is, let's say, a `Sort` node and again recursion is needed to obtain an input row. The child node of the `Sort` might be a `SeqScan` node, representing actual reading of a table. Execution of this node causes the executor to fetch a row from the table and return it up to the calling node. The `Sort` node will repeatedly call its child to obtain all the rows to be sorted. When the input is exhausted (as indicated by the child node returning a `NULL` instead of a row), the `Sort` code performs the sort, and

finally is able to return its first output row, namely the first one in sorted order. It keeps the remaining rows stored so that it can deliver them in sorted order in response to later demands.

The `MergeJoin` node similarly demands the first row from its right subplan. Then it compares the two rows to see if they can be joined; if so, it returns a join row to its caller. On the next call, or immediately if it cannot join the current pair of inputs, it advances to the next row of one table or the other (depending on how the comparison came out), and again checks for a match. Eventually, one subplan or the other is exhausted, and the `MergeJoin` node returns `NULL` to indicate that no more join rows can be formed.

Complex queries can involve many levels of plan nodes, but the general approach is the same: each node computes and returns its next output row each time it is called. Each node is also responsible for applying any selection or projection expressions that were assigned to it by the planner.

The executor mechanism is used to evaluate all four basic SQL query types: `SELECT`, `INSERT`, `UPDATE`, and `DELETE`. For `SELECT`, the top-level executor code only needs to send each row returned by the query plan tree off to the client. `INSERT ... SELECT`, `UPDATE`, and `DELETE` are effectively `SELECT`s under a special top-level plan node called `ModifyTable`.

`INSERT ... SELECT` feeds the rows up to `ModifyTable` for insertion. For `UPDATE`, the planner arranges that each computed row includes all the updated column values, plus the *TID* (tuple ID, or row ID) of the original target row; this data is fed up to the `ModifyTable` node, which uses the information to create a new updated row and mark the old row deleted. For `DELETE`, the only column that is actually returned by the plan is the TID, and the `ModifyTable` node simply uses the TID to visit each target row and mark it deleted.

A simple `INSERT ... VALUES` command creates a trivial plan tree consisting of a single `Result` node, which computes just one result row, feeding that up to `ModifyTable` to perform the insertion.

---

## Chapter 54. System Catalogs

The system catalogs are the place where a relational database management system stores schema meta-data, such as information about tables and columns, and internal bookkeeping information. Postgres Pro's system catalogs are regular tables. You can drop and recreate the tables, add columns, insert and update values, and severely mess up your system that way. Normally, one should not change the system catalogs by hand, there are normally SQL commands to do that. (For example, `CREATE DATABASE` inserts a row into the `pg_database` catalog — and actually creates the database on disk.) There are some exceptions for particularly esoteric operations, but many of those have been made available as SQL commands over time, and so the need for direct manipulation of the system catalogs is ever decreasing.

### 54.1. Overview

Table 54.1 lists the system catalogs. More detailed documentation of each catalog follows below.

Most system catalogs are copied from the template database during database creation and are thereafter database-specific. A few catalogs are physically shared across all databases in a cluster; these are noted in the descriptions of the individual catalogs.

**Table 54.1. System Catalogs**

| Catalog Name                         | Purpose                                                                                 |
|--------------------------------------|-----------------------------------------------------------------------------------------|
| <code>pg_aggregate</code>            | aggregate functions                                                                     |
| <code>pg_am</code>                   | relation access methods                                                                 |
| <code>pg_amop</code>                 | access method operators                                                                 |
| <code>pg_amproc</code>               | access method support functions                                                         |
| <code>pg_attrdef</code>              | column default values                                                                   |
| <code>pg_attribute</code>            | table columns (“attributes”)                                                            |
| <code>pg_authid</code>               | authorization identifiers (roles)                                                       |
| <code>pg_auth_members</code>         | authorization identifier membership relationships                                       |
| <code>pg_cast</code>                 | casts (data type conversions)                                                           |
| <code>pg_class</code>                | tables, indexes, sequences, views (“relations”)                                         |
| <code>pg_collation</code>            | collations (locale information)                                                         |
| <code>pg_constraint</code>           | check constraints, unique constraints, primary key constraints, foreign key constraints |
| <code>pg_conversion</code>           | encoding conversion information                                                         |
| <code>pg_database</code>             | databases within this database cluster                                                  |
| <code>pg_db_role_setting</code>      | per-role and per-database settings                                                      |
| <code>pg_default_acl</code>          | default privileges for object types                                                     |
| <code>pg_depend</code>               | dependencies between database objects                                                   |
| <code>pg_description</code>          | descriptions or comments on database objects                                            |
| <code>pg_enum</code>                 | enum label and value definitions                                                        |
| <code>pg_event_trigger</code>        | event triggers                                                                          |
| <code>pg_extension</code>            | installed extensions                                                                    |
| <code>pg_foreign_data_wrapper</code> | foreign-data wrapper definitions                                                        |
| <code>pg_foreign_server</code>       | foreign server definitions                                                              |
| <code>pg_foreign_table</code>        | additional foreign table information                                                    |
| <code>pg_index</code>                | additional index information                                                            |

| Catalog Name                            | Purpose                                                   |
|-----------------------------------------|-----------------------------------------------------------|
| <a href="#">pg_inherits</a>             | table inheritance hierarchy                               |
| <a href="#">pg_init_privs</a>           | object initial privileges                                 |
| <a href="#">pg_language</a>             | languages for writing functions                           |
| <a href="#">pg_largeobject</a>          | data pages for large objects                              |
| <a href="#">pg_largeobject_metadata</a> | metadata for large objects                                |
| <a href="#">pg_namespace</a>            | schemas                                                   |
| <a href="#">pg_opclass</a>              | access method operator classes                            |
| <a href="#">pg_operator</a>             | operators                                                 |
| <a href="#">pg_opfamily</a>             | access method operator families                           |
| <a href="#">pg_partitioned_table</a>    | information about partition key of tables                 |
| <a href="#">pg_policy</a>               | row-security policies                                     |
| <a href="#">pg_proc</a>                 | functions and procedures                                  |
| <a href="#">pg_profile</a>              | profiles, a set of authentication restrictions            |
| <a href="#">pg_publication</a>          | publications for logical replication                      |
| <a href="#">pg_publication_rel</a>      | relation to publication mapping                           |
| <a href="#">pg_range</a>                | information about range types                             |
| <a href="#">pg_replication_origin</a>   | registered replication origins                            |
| <a href="#">pg_rewrite</a>              | query rewrite rules                                       |
| <a href="#">pg_role_password</a>        | roles password history                                    |
| <a href="#">pg_seclabel</a>             | security labels on database objects                       |
| <a href="#">pg_sequence</a>             | information about sequences                               |
| <a href="#">pg_shdepend</a>             | dependencies on shared objects                            |
| <a href="#">pg_shdescription</a>        | comments on shared objects                                |
| <a href="#">pg_shseclabel</a>           | security labels on shared database objects                |
| <a href="#">pg_statistic</a>            | planner statistics                                        |
| <a href="#">pg_statistic_ext</a>        | extended planner statistics (definition)                  |
| <a href="#">pg_statistic_ext_data</a>   | extended planner statistics (built statistics)            |
| <a href="#">pg_subscription</a>         | logical replication subscriptions                         |
| <a href="#">pg_subscription_rel</a>     | relation state for subscriptions                          |
| <a href="#">pg_tablespace</a>           | tablespaces within this database cluster                  |
| <a href="#">pg_transform</a>            | transforms (data type to procedural language conversions) |
| <a href="#">pg_trigger</a>              | triggers                                                  |
| <a href="#">pg_ts_config</a>            | text search configurations                                |
| <a href="#">pg_ts_config_map</a>        | text search configurations' token mappings                |
| <a href="#">pg_ts_dict</a>              | text search dictionaries                                  |
| <a href="#">pg_ts_parser</a>            | text search parsers                                       |
| <a href="#">pg_ts_template</a>          | text search templates                                     |
| <a href="#">pg_type</a>                 | data types                                                |
| <a href="#">pg_user_mapping</a>         | mappings of users to foreign servers                      |

## 54.2. pg\_aggregate

The catalog `pg_aggregate` stores information about aggregate functions. An aggregate function is a function that operates on a set of values (typically one column from each row that matches a query condition) and returns a single value computed from all these values. Typical aggregate functions are `sum`, `count`, and `max`. Each entry in `pg_aggregate` is an extension of an entry in `pg_proc`. The `pg_proc` entry carries the aggregate's name, input and output data types, and other information that is similar to ordinary functions.

**Table 54.2. `pg_aggregate` Columns**

| Column Type                                                                                                                 | Description                                                                                                                                                                                                                                                                                                                                    |
|-----------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>aggfnoid regproc</code> (references <code>pg_proc .oid</code> )<br><code>pg_proc</code> OID of the aggregate function |                                                                                                                                                                                                                                                                                                                                                |
| <code>aggkind char</code>                                                                                                   | Aggregate kind: <code>n</code> for “normal” aggregates, <code>o</code> for “ordered-set” aggregates, or <code>h</code> for “hypothetical-set” aggregates                                                                                                                                                                                       |
| <code>aggnumdirectargs int2</code>                                                                                          | Number of direct (non-aggregated) arguments of an ordered-set or hypothetical-set aggregate, counting a variadic array as one argument. If equal to <code>pronargs</code> , the aggregate must be variadic and the variadic array describes the aggregated arguments as well as the final direct arguments. Always zero for normal aggregates. |

| agginitval text                                             | The initial value of the transition state. This is a text field containing the initial value in its external string representation. If this field is null, the transition state value starts out null.                           |
| aggminitval text                                            | The initial value of the transition state for moving-aggregate mode. This is a text field containing the initial value in its external string representation. If this field is null, the transition state value starts out null. |

New aggregate functions are registered with the [CREATE AGGREGATE](#) command. See [Section 40.12](#) for more information about writing aggregate functions and the meaning of the transition functions, etc.

## 54.3. pg\_am

The catalog `pg_am` stores information about relation access methods. There is one row for each access method supported by the system. Currently, only tables and indexes have access methods. The requirements for table and index access methods are discussed in detail in [Chapter 61](#) and [Chapter 62](#) respectively.

**Table 54.3. `pg_am` Columns**

| Column Type                                                 | Description                                                                                     |
|-------------------------------------------------------------|-------------------------------------------------------------------------------------------------|
| oid oid                                                     | Row identifier                                                                                  |
| amname name                                                 | Name of the access method                                                                       |
| amhandler regproc (references <a href="#">pg_proc</a> .oid) | OID of a handler function that is responsible for supplying information about the access method |
| amtype char                                                 | t = table (including materialized views), i = index.                                            |

### Note

Before Postgres Pro 9.6, `pg_am` contained many additional columns representing properties of index access methods. That data is now only directly visible at the C code level. However, `pg_index_column_has_property()` and related functions have been added to allow SQL queries to inspect index access method properties; see [Table 9.70](#).

## 54.4. pg\_amop

The catalog `pg_amop` stores information about operators associated with access method operator families. There is one row for each operator that is a member of an operator family. A family member can be either a *search* operator or an *ordering* operator. An operator can appear in more than one family, but cannot appear in more than one search position nor more than one ordering position within a family. (It is allowed, though unlikely, for an operator to be used for both search and ordering purposes.)

**Table 54.4. `pg_amop` Columns**

| Column                          | Type                                                        | Description                                                                                                  |

| <code>amopopr</code>            | <code>oid</code> (references <code>pg_operator</code> .oid) | OID of the operator                                                                                          |
| <code>amopmethod</code>         | <code>oid</code> (references <code>pg_am</code> .oid)       | Index access method operator family is for                                                                   |
| <code>amopsortfamily</code>     | <code>oid</code> (references <code>pg_opfamily</code> .oid) | The B-tree operator family this entry sorts according to, if an ordering operator; zero if a search operator |

A “search” operator entry indicates that an index of this operator family can be searched to find all rows satisfying `WHERE indexed_column operator constant`. Obviously, such an operator must return boolean, and its left-hand input type must match the index's column data type.

An “ordering” operator entry indicates that an index of this operator family can be scanned to return rows in the order represented by `ORDER BY indexed_column operator constant`. Such an operator could return any sortable data type, though again its left-hand input type must match the index's column data type. The exact semantics of the `ORDER BY` are specified by the `amopsortfamily` column, which must reference a B-tree operator family for the operator's result type.

### Note

At present, it's assumed that the sort order for an ordering operator is the default for the referenced operator family, i.e., `ASC NULLS LAST`. This might someday be relaxed by adding additional columns to specify sort options explicitly.

An entry's `amopmethod` must match the `opfmethod` of its containing operator family (including `amopmethod` here is an intentional denormalization of the catalog structure for performance reasons). Also, `amoplefttype` and `amoprightrighttype` must match the `oprleft` and `oprright` fields of the referenced `pg_operator` entry.

## 54.5. `pg_amproc`

The catalog `pg_amproc` stores information about support functions associated with access method operator families. There is one row for each support function belonging to an operator family.

**Table 54.5. pg\_amproc Columns**

| Column Type                                                    | Description                                       |
|----------------------------------------------------------------|---------------------------------------------------|
| oid oid                                                        | Row identifier                                    |
| amprocfamily oid (references <a href="#">pg_opfamily</a> .oid) | The operator family this entry is for             |
| amproclefttype oid (references <a href="#">pg_type</a> .oid)   | Left-hand input data type of associated operator  |
| amprocrighttype oid (references <a href="#">pg_type</a> .oid)  | Right-hand input data type of associated operator |
| amprocnum int2                                                 | Support function number                           |
| amproc regproc (references <a href="#">pg_proc</a> .oid)       | OID of the function                               |

The usual interpretation of the `amproclefttype` and `amprocrighttype` fields is that they identify the left and right input types of the operator(s) that a particular support function supports. For some access methods these match the input data type(s) of the support function itself, for others not. There is a notion of “default” support functions for an index, which are those with `amproclefttype` and `amprocrighttype` both equal to the index operator class's `opcintype`.

## 54.6. pg\_attrdef

The catalog `pg_attrdef` stores column default values. The main information about columns is stored in [pg\\_attribute](#). Only columns for which a default value has been explicitly set will have an entry here.

**Table 54.6. pg\_attrdef Columns**

| Column Type                                                  | Description                                                                                                                                               |
|--------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------|
| oid oid                                                      | Row identifier                                                                                                                                            |
| adrelid oid (references <a href="#">pg_class</a> .oid)       | The table this column belongs to                                                                                                                          |
| adnum int2 (references <a href="#">pg_attribute</a> .attnum) | The number of the column                                                                                                                                  |
| adbin pg_node_tree                                           | The column default value, in <code>nodeToString()</code> representation. Use <code>pg_get_expr(adbin, adrelid)</code> to convert it to an SQL expression. |

## 54.7. pg\_attribute

The catalog `pg_attribute` stores information about table columns. There will be exactly one `pg_attribute` row for every column in every table in the database. (There will also be attribute entries for indexes, and indeed all objects that have [pg\\_class](#) entries.)

The term attribute is equivalent to column and is used for historical reasons.

**Table 54.7. pg\_attribute Columns**

| Column Type                                             | Description                      |
|---------------------------------------------------------|----------------------------------|
| attrelid oid (references <a href="#">pg_class</a> .oid) | The table this column belongs to |

| Column Type                                                      | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
|------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>attname</code> name                                        | The column name                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| <code>atttypid</code> oid (references <code>pg_type</code> .oid) | The data type of this column (zero for a dropped column)                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| <code>attstattarget</code> int4                                  | <code>attstattarget</code> controls the level of detail of statistics accumulated for this column by <a href="#">ANALYZE</a> . A zero value indicates that no statistics should be collected. A negative value says to use the system default statistics target. The exact meaning of positive values is data type-dependent. For scalar data types, <code>attstattarget</code> is both the target number of “most common values” to collect, and the target number of histogram bins to create. |
| <code>attlen</code> int2                                         | A copy of <code>pg_type.typelen</code> of this column's type                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| <code>attnum</code> int2                                         | The number of the column. Ordinary columns are numbered from 1 up. System columns, such as <code>ctid</code> , have (arbitrary) negative numbers.                                                                                                                                                                                                                                                                                                                                                |
| <code>attn_dims</code> int4                                      | Number of dimensions, if the column is an array type; otherwise 0. (Presently, the number of dimensions of an array is not enforced, so any nonzero value effectively means “it's an array”.)                                                                                                                                                                                                                                                                                                    |
| <code>attcacheoff</code> int4                                    | Always -1 in storage, but when loaded into a row descriptor in memory this might be updated to cache the offset of the attribute within the row                                                                                                                                                                                                                                                                                                                                                  |
| <code>atttypmod</code> int4                                      | <code>atttypmod</code> records type-specific data supplied at table creation time (for example, the maximum length of a <code>varchar</code> column). It is passed to type-specific input functions and length coercion functions. The value will generally be -1 for types that do not need <code>atttypmod</code> .                                                                                                                                                                            |
| <code>attbyval</code> bool                                       | A copy of <code>pg_type.typbyval</code> of this column's type                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| <code>attalign</code> char                                       | A copy of <code>pg_type.typalign</code> of this column's type                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| <code>attstorage</code> char                                     | Normally a copy of <code>pg_type.typstorage</code> of this column's type. For TOAST-able data types, this can be altered after column creation to control storage policy.                                                                                                                                                                                                                                                                                                                        |
| <code>attcompression</code> char                                 | The current compression method of the column. Typically this is <code>'\0'</code> to specify use of the current default setting (see <a href="#">default_toast_compression</a> ). Otherwise, <code>'p'</code> selects <code>pglz</code> compression, while <code>'l'</code> selects <code>LZ4</code> compression. However, this field is ignored whenever <code>attstorage</code> does not allow compression.                                                                                    |
| <code>attnotnull</code> bool                                     | This represents a not-null constraint.                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| <code>atthasdef</code> bool                                      | This column has a default expression or generation expression, in which case there will be a corresponding entry in the <code>pg_attrdef</code> catalog that actually defines the expression. (Check <code>attgenerated</code> to determine whether this is a default or a generation expression.)                                                                                                                                                                                               |
| <code>atthasmissing</code> bool                                  | This column has a value which is used where the column is entirely missing from the row, as happens when a column is added with a non-volatile <code>DEFAULT</code> value after the row is created. The actual value used is stored in the <code>attmissingval</code> column.                                                                                                                                                                                                                    |

| Column Type                                                               | Description                                                                                                                                                                                                                                                                                                                           |
|---------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>attidentity</code> char                                             | If a zero byte (' '), then not an identity column. Otherwise, <code>a</code> = generated always, <code>d</code> = generated by default.                                                                                                                                                                                               |
| <code>attgenerated</code> char                                            | If a zero byte (' '), then not a generated column. Otherwise, <code>s</code> = stored. (Other values might be added in the future.)                                                                                                                                                                                                   |
| <code>attisdropped</code> bool                                            | This column has been dropped and is no longer valid. A dropped column is still physically present in the table, but is ignored by the parser and so cannot be accessed via SQL.                                                                                                                                                       |
| <code>attislocal</code> bool                                              | This column is defined locally in the relation. Note that a column can be locally defined and inherited simultaneously.                                                                                                                                                                                                               |
| <code>attinhcount</code> int4                                             | The number of direct ancestors this column has. A column with a nonzero number of ancestors cannot be dropped nor renamed.                                                                                                                                                                                                            |
| <code>attcollation</code> oid (references <code>pg_collation</code> .oid) | The defined collation of the column, or zero if the column is not of a collatable data type                                                                                                                                                                                                                                           |
| <code>attacl</code> aclitem[]                                             | Column-level access privileges, if any have been granted specifically on this column                                                                                                                                                                                                                                                  |
| <code>attoptions</code> text[]                                            | Attribute-level options, as “keyword=value” strings                                                                                                                                                                                                                                                                                   |
| <code>attfdwoptions</code> text[]                                         | Attribute-level foreign data wrapper options, as “keyword=value” strings                                                                                                                                                                                                                                                              |
| <code>attmissingval</code> anyarray                                       | This column has a one element array containing the value used when the column is entirely missing from the row, as happens when the column is added with a non-volatile <code>DEFAULT</code> value after the row is created. The value is only used when <code>atthasmissing</code> is true. If there is no value the column is null. |

In a dropped column's `pg_attribute` entry, `atttypid` is reset to zero, but `attlen` and the other fields copied from `pg_type` are still valid. This arrangement is needed to cope with the situation where the dropped column's data type was later dropped, and so there is no `pg_type` row anymore. `attlen` and the other fields can be used to interpret the contents of a row of the table.

## 54.8. `pg_authid`

The catalog `pg_authid` contains information about database authorization identifiers (roles). A role subsumes the concepts of “users” and “groups”. A user is essentially just a role with the `rolcanlogin` flag set. Any role (with or without `rolcanlogin`) can have other roles as members; see `pg_auth_members`.

Since this catalog contains passwords, it must not be publicly readable. `pg_roles` is a publicly readable view on `pg_authid` that blanks out the password field.

[Chapter 21](#) contains detailed information about user and privilege management.

Because user identities are cluster-wide, `pg_authid` is shared across all databases of a cluster: there is only one copy of `pg_authid` per cluster, not one per database.

**Table 54.8. `pg_authid` Columns**

| Column Type          | Description |
|----------------------|-------------|
| <code>oid</code> oid |             |

| Column             | Type                                                    | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|--------------------|---------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                    |                                                         | Row identifier                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| rolname            | name                                                    | Role name                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| rolsuper           | bool                                                    | Role has superuser privileges                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| rolinherit         | bool                                                    | Role automatically inherits privileges of roles it is a member of                                                                                                                                                                                                                                                                                                                                                                                                  |

| rolpasssetat       | timestampz                                              | Password set time (only used for password authentication); null if password is not set.                                                                                                                                                                                                                                                                                                                                                                            |

For an MD5 encrypted password, `rolpassword` column will begin with the string `md5` followed by a 32-character hexadecimal MD5 hash. The MD5 hash will be of the user's password concatenated to

their user name. For example, if user `joe` has password `xyzyzy`, Postgres Pro will store the md5 hash of `xyzyzyjoe`.

If the password is encrypted with SCRAM-SHA-256, it has the format:

```
SCRAM-SHA-256$<iteration count>:<salt>$<StoredKey>:<ServerKey>
```

where *salt*, *StoredKey* and *ServerKey* are in Base64 encoded format. This format is the same as that specified by [RFC 5803](#).

## 54.9. pg\_auth\_members

The catalog `pg_auth_members` shows the membership relations between roles. Any non-circular set of relationships is allowed.

Because user identities are cluster-wide, `pg_auth_members` is shared across all databases of a cluster: there is only one copy of `pg_auth_members` per cluster, not one per database.

**Table 54.9. pg\_auth\_members Columns**

| Column Type                                                        | Description                                                                       |
|--------------------------------------------------------------------|-----------------------------------------------------------------------------------|
| <code>roleid oid</code> (references <code>pg_authid .oid</code> )  | ID of a role that has a member                                                    |
| <code>member oid</code> (references <code>pg_authid .oid</code> )  | ID of a role that is a member of <code>roleid</code>                              |
| <code>grantor oid</code> (references <code>pg_authid .oid</code> ) | ID of the role that granted this membership                                       |
| <code>admin_option bool</code>                                     | True if <code>member</code> can grant membership in <code>roleid</code> to others |

## 54.10. pg\_cast

The catalog `pg_cast` stores data type conversion paths, both built-in and user-defined.

It should be noted that `pg_cast` does not represent every type conversion that the system knows how to perform; only those that cannot be deduced from some generic rule. For example, casting between a domain and its base type is not explicitly represented in `pg_cast`. Another important exception is that “automatic I/O conversion casts”, those performed using a data type's own I/O functions to convert to or from `text` or other string types, are not explicitly represented in `pg_cast`.

**Table 54.10. pg\_cast Columns**

| Column Type                                                         | Description                                                                                                                                                                                                                                                                                                                 |
|---------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>oid oid</code>                                                | Row identifier                                                                                                                                                                                                                                                                                                              |
| <code>castsouce oid</code> (references <code>pg_type .oid</code> )  | OID of the source data type                                                                                                                                                                                                                                                                                                 |
| <code>casttarget oid</code> (references <code>pg_type .oid</code> ) | OID of the target data type                                                                                                                                                                                                                                                                                                 |
| <code>castfunc oid</code> (references <code>pg_proc .oid</code> )   | The OID of the function to use to perform this cast. Zero is stored if the cast method doesn't require a function.                                                                                                                                                                                                          |
| <code>castcontext char</code>                                       | Indicates what contexts the cast can be invoked in. <code>e</code> means only as an explicit cast (using <code>CAST</code> or <code>::</code> syntax). <code>a</code> means implicitly in assignment to a target column, as well as explicitly. <code>i</code> means implicitly in expressions, as well as the other cases. |

| Column Type                               | Description                                                                                                                                                                                                                                                                                |
|-------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>castmethod</code> <code>char</code> | Indicates how the cast is performed. <code>f</code> means that the function specified in the <code>castfunc</code> field is used. <code>i</code> means that the input/output functions are used. <code>b</code> means that the types are binary-coercible, thus no conversion is required. |

The cast functions listed in `pg_cast` must always take the cast source type as their first argument type, and return the cast destination type as their result type. A cast function can have up to three arguments. The second argument, if present, must be type `integer`; it receives the type modifier associated with the destination type, or -1 if there is none. The third argument, if present, must be type `boolean`; it receives `true` if the cast is an explicit cast, `false` otherwise.

It is legitimate to create a `pg_cast` entry in which the source and target types are the same, if the associated function takes more than one argument. Such entries represent “length coercion functions” that coerce values of the type to be legal for a particular type modifier value.

When a `pg_cast` entry has different source and target types and a function that takes more than one argument, it represents converting from one type to another and applying a length coercion in a single step. When no such entry is available, coercion to a type that uses a type modifier involves two steps, one to convert between data types and a second to apply the modifier.

## 54.11. `pg_class`

The catalog `pg_class` describes tables and other objects that have columns or are otherwise similar to a table. This includes indexes (but see also [pg\\_index](#)), sequences (but see also [pg\\_sequence](#)), views, materialized views, composite types, and TOAST tables; see `relkind`. Below, when we mean all of these kinds of objects we speak of “relations”. Not all of `pg_class`'s columns are meaningful for all relation kinds.

**Table 54.11. `pg_class` Columns**

| Column Type                                                                                                | Description                                                                                                                                                                        |
|------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>oid</code> <code>oid</code>                                                                          | Row identifier                                                                                                                                                                     |
| <code>relname</code> <code>name</code>                                                                     | Name of the table, index, view, etc.                                                                                                                                               |
| <code>relnamespace</code> <code>oid</code> (references <a href="#">pg_namespace</a> . <code>oid</code> )   | The OID of the namespace that contains this relation                                                                                                                               |
| <code>reltype</code> <code>oid</code> (references <a href="#">pg_type</a> . <code>oid</code> )             | The OID of the data type that corresponds to this table's row type, if any; zero for indexes, sequences, and toast tables, which have no <code>pg_type</code> entry                |
| <code>reloftype</code> <code>oid</code> (references <a href="#">pg_type</a> . <code>oid</code> )           | For typed tables, the OID of the underlying composite type; zero for all other relations                                                                                           |
| <code>relowner</code> <code>oid</code> (references <a href="#">pg_authid</a> . <code>oid</code> )          | Owner of the relation                                                                                                                                                              |
| <code>relam</code> <code>oid</code> (references <a href="#">pg_am</a> . <code>oid</code> )                 | If this is a table or an index, the access method used (heap, B-tree, hash, etc.); otherwise zero (zero occurs for sequences, as well as relations without storage, such as views) |
| <code>relfilenode</code> <code>oid</code>                                                                  | Name of the on-disk file of this relation; zero means this is a “mapped” relation whose disk file name is determined by low-level state                                            |
| <code>reltablespace</code> <code>oid</code> (references <a href="#">pg_tablespace</a> . <code>oid</code> ) |                                                                                                                                                                                    |

| Column Type                                               | Description                                                                                                                                                                                                                                                                                                                                              |
|-----------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                                           | The tablespace in which this relation is stored. If zero, the database's default tablespace is implied. Not meaningful if the relation has no on-disk file, except for partitioned tables, where this is the tablespace in which partitions will be created when one is not specified in the creation command.                                           |
| relpages int4                                             | Size of the on-disk representation of this table in pages (of size <code>BLCKSZ</code> ). This is only an estimate used by the planner. It is updated by <code>VACUUM</code> , <code>ANALYZE</code> , and a few DDL commands such as <code>CREATE INDEX</code> .                                                                                         |
| reltuples float4                                          | Number of live rows in the table. This is only an estimate used by the planner. It is updated by <code>VACUUM</code> , <code>ANALYZE</code> , and a few DDL commands such as <code>CREATE INDEX</code> . If the table has never yet been vacuumed or analyzed, <code>reltuples</code> contains <code>-1</code> indicating that the row count is unknown. |
| relallvisible int4                                        | Number of pages that are marked all-visible in the table's visibility map. This is only an estimate used by the planner. It is updated by <code>VACUUM</code> , <code>ANALYZE</code> , and a few DDL commands such as <code>CREATE INDEX</code> .                                                                                                        |
| reltoastrelid oid (references <code>pg_class</code> .oid) | OID of the TOAST table associated with this table, zero if none. The TOAST table stores large attributes "out of line" in a secondary table.                                                                                                                                                                                                             |
| relhasindex bool                                          | True if this is a table and it has (or recently had) any indexes                                                                                                                                                                                                                                                                                         |
| relisshared bool                                          | True if this table is shared across all databases in the cluster. Only certain system catalogs (such as <code>pg_database</code> ) are shared.                                                                                                                                                                                                           |
| relpersistence char                                       | p = permanent table, u = unlogged table, t = temporary table, c = constant table                                                                                                                                                                                                                                                                         |
| relkind char                                              | r = ordinary table, i = index, s = sequence, t = TOAST table, v = view, m = materialized view, c = composite type, f = foreign table, p = partitioned table, I = partitioned index                                                                                                                                                                       |
| relnatts int2                                             | Number of user columns in the relation (system columns not counted). There must be this many corresponding entries in <code>pg_attribute</code> . See also <code>pg_attribute</code> .attnum.                                                                                                                                                            |
| relchecks int2                                            | Number of <code>CHECK</code> constraints on the table; see <code>pg_constraint</code> catalog                                                                                                                                                                                                                                                            |
| relhasrules bool                                          | True if table has (or once had) rules; see <code>pg_rewrite</code> catalog                                                                                                                                                                                                                                                                               |
| relhastriggers bool                                       | True if table has (or once had) triggers; see <code>pg_trigger</code> catalog                                                                                                                                                                                                                                                                            |
| relhassubclass bool                                       | True if table or index has (or once had) any inheritance children                                                                                                                                                                                                                                                                                        |
| relrowsecurity bool                                       | True if table has row-level security enabled; see <code>pg_policy</code> catalog                                                                                                                                                                                                                                                                         |
| relforcerowsecurity bool                                  | True if row-level security (when enabled) will also apply to table owner; see <code>pg_policy</code> catalog                                                                                                                                                                                                                                             |
| relispopulated bool                                       | True if relation is populated (this is true for all relations other than some materialized views)                                                                                                                                                                                                                                                        |

| Column Type                                                          | Description                                                                                                                                                                                                                                                                                                   |
|----------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>relreplident char</code>                                       | Columns used to form “replica identity” for rows: <code>d</code> = default (primary key, if any), <code>n</code> = nothing, <code>f</code> = all columns, <code>i</code> = index with <code>indisreplident</code> set (same as nothing if the index used has been dropped)                                    |
| <code>relispartition bool</code>                                     | True if table or index is a partition                                                                                                                                                                                                                                                                         |
| <code>relrewrite oid</code> (references <code>pg_class .oid</code> ) | For new relations being written during a DDL operation that requires a table rewrite, this contains the OID of the original relation; otherwise zero. That state is only visible internally; this field should never contain anything other than zero for a user-visible relation.                            |
| <code>relfrozenxid xid</code>                                        | All transaction IDs before this one have been replaced with a permanent (“frozen”) transaction ID in this table. This is used to track whether the table needs to be vacuumed in order to allow <code>pg_xact</code> to be shrunk. Zero ( <code>InvalidTransactionId</code> ) if the relation is not a table. |
| <code>relminmxid xid</code>                                          | All multixact IDs before this one have been replaced by a transaction ID in this table. This is used to track whether the table needs to be vacuumed in order to allow <code>pg_multixact</code> to be shrunk. Zero ( <code>InvalidMultiXactId</code> ) if the relation is not a table.                       |
| <code>relacl aclitem[]</code>                                        | Access privileges; see <a href="#">Section 5.7</a> for details                                                                                                                                                                                                                                                |
| <code>reloptions text[]</code>                                       | Access-method-specific options, as “keyword=value” strings                                                                                                                                                                                                                                                    |
| <code>relpartbound pg_node_tree</code>                               | If table is a partition (see <code>relispartition</code> ), internal representation of the partition bound                                                                                                                                                                                                    |

Several of the Boolean flags in `pg_class` are maintained lazily: they are guaranteed to be true if that's the correct state, but may not be reset to false immediately when the condition is no longer true. For example, `relhasindex` is set by `CREATE INDEX`, but it is never cleared by `DROP INDEX`. Instead, `VACUUM` clears `relhasindex` if it finds the table has no indexes. This arrangement avoids race conditions and improves concurrency.

## 54.12. pg\_collation

The catalog `pg_collation` describes the available collations, which are essentially mappings from an SQL name to operating system locale categories. See [Section 23.2](#) for more information.

**Table 54.12. `pg_collation` Columns**

| Column Type                                                                 | Description                                                                                               |
|-----------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------|
| <code>oid oid</code>                                                        | Row identifier                                                                                            |
| <code>collname name</code>                                                  | Collation name (unique per namespace and encoding)                                                        |
| <code>collnamespace oid</code> (references <code>pg_namespace .oid</code> ) | The OID of the namespace that contains this collation                                                     |
| <code>collowner oid</code> (references <code>pg_authid .oid</code> )        | Owner of the collation                                                                                    |
| <code>collprovider char</code>                                              | Provider of the collation: <code>d</code> = database default, <code>c</code> = libc, <code>i</code> = icu |
| <code>collisdeterministic bool</code>                                       |                                                                                                           |

| Column Type       | Description                                                                                                                                                                                                    |
|-------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                   | Is the collation deterministic?                                                                                                                                                                                |
| collencoding int4 | Encoding in which the collation is applicable, or -1 if it works for any encoding                                                                                                                              |
| collcollate name  | LC_COLLATE for this collation object                                                                                                                                                                           |
| collctype name    | LC_CTYPE for this collation object                                                                                                                                                                             |
| collversion text  | Provider-specific version of the collation. This is recorded when the collation is created and then checked when it is used, to detect changes in the collation definition that could lead to data corruption. |

Note that the unique key on this catalog is (`collname`, `collencoding`, `collnamespace`) not just (`collname`, `collnamespace`). Postgres Pro generally ignores all collations that do not have `collencoding` equal to either the current database's encoding or -1, and creation of new entries with the same name as an entry with `collencoding` = -1 is forbidden. Therefore it is sufficient to use a qualified SQL name (*schema.name*) to identify a collation, even though this is not unique according to the catalog definition. The reason for defining the catalog this way is that `initdb` fills it in at cluster initialization time with entries for all locales available on the system, so it must be able to hold entries for all encodings that might ever be used in the cluster.

In the `template0` database, it could be useful to create collations whose encoding does not match the database encoding, since they could match the encodings of databases later cloned from `template0`. This would currently have to be done manually.

## 54.13. pg\_constraint

The catalog `pg_constraint` stores check, primary key, unique, foreign key, and exclusion constraints on tables. (Column constraints are not treated specially. Every column constraint is equivalent to some table constraint.) Not-null constraints are represented in the `pg_attribute` catalog, not here.

User-defined constraint triggers (created with `CREATE CONSTRAINT TRIGGER`) also give rise to an entry in this table.

Check constraints on domains are stored here, too.

**Table 54.13. pg\_constraint Columns**

| Column Type                                                  | Description                                                                                                                                           |
|--------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------|
| oid oid                                                      | Row identifier                                                                                                                                        |
| conname name                                                 | Constraint name (not necessarily unique!)                                                                                                             |
| connamespace oid (references <code>pg_namespace</code> .oid) | The OID of the namespace that contains this constraint                                                                                                |
| contype char                                                 | c = check constraint, f = foreign key constraint, p = primary key constraint, u = unique constraint, t = constraint trigger, x = exclusion constraint |
| condeferrable bool                                           | Is the constraint deferrable?                                                                                                                         |
| condeferred bool                                             | Is the constraint deferred by default?                                                                                                                |

| Column Type                                                   | Description                                                                                                                                                                         |
|---------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| convalidated bool                                             | Has the constraint been validated? Currently, can be false only for foreign keys and CHECK constraints                                                                              |

| confmatchtype char                                            | Foreign key match type: f = full, p = partial, s = simple                                                                                                                           |
| conislocal bool                                               | This constraint is defined locally for the relation. Note that a constraint can be locally defined and inherited simultaneously.                                                    |
| coninhcount int4                                              | The number of direct inheritance ancestors this constraint has. A constraint with a nonzero number of ancestors cannot be dropped nor renamed.                                      |
| connoinherit bool                                             | This constraint is defined locally for the relation. It is a non-inheritable constraint.                                                                                            |
| conkey int2[] (references <code>pg_attribute</code> .attnum)  | If a table constraint (including foreign keys, but not constraint triggers), list of the constrained columns                                                                        |
| confkey int2[] (references <code>pg_attribute</code> .attnum) | If a foreign key, list of the referenced columns                                                                                                                                    |
| conpfeqop oid[] (references <code>pg_operator</code> .oid)    | If a foreign key, list of the equality operators for PK = FK comparisons                                                                                                            |
| conppeqop oid[] (references <code>pg_operator</code> .oid)    | If a foreign key, list of the equality operators for PK = PK comparisons                                                                                                            |
| conffeqop oid[] (references <code>pg_operator</code> .oid)    | If a foreign key, list of the equality operators for FK = FK comparisons                                                                                                            |
| conexcllop oid[] (references <code>pg_operator</code> .oid)   | If an exclusion constraint, list of the per-column exclusion operators                                                                                                              |
| conbin pg_node_tree                                           | If a check constraint, an internal representation of the expression. (It's recommended to use <code>pg_get_constraintdef()</code> to extract the definition of a check constraint.) |

In the case of an exclusion constraint, `conkey` is only useful for constraint elements that are simple column references. For other cases, a zero appears in `conkey` and the associated index must be consulted to discover the expression that is constrained. (`conkey` thus has the same contents as `pg_index.indkey` for the index.)

### Note

`pg_class.relchecks` needs to agree with the number of check-constraint entries found in this table for each relation.

## 54.14. pg\_conversion

The catalog `pg_conversion` describes encoding conversion functions. See [CREATE CONVERSION](#) for more information.

**Table 54.14. pg\_conversion Columns**

| Column Type                                                  | Description                                            |
|--------------------------------------------------------------|--------------------------------------------------------|
| <code>oid oid</code>                                         | Row identifier                                         |
| <code>conname name</code>                                    | Conversion name (unique within a namespace)            |
| <code>connamespace oid (references pg_namespace .oid)</code> | The OID of the namespace that contains this conversion |
| <code>conowner oid (references pg_authid .oid)</code>        | Owner of the conversion                                |
| <code>conforencoding int4</code>                             | Source encoding ID                                     |
| <code>contoencoding int4</code>                              | Destination encoding ID                                |
| <code>conproc regproc (references pg_proc .oid)</code>       | Conversion function                                    |
| <code>condefault bool</code>                                 | True if this is the default conversion                 |

## 54.15. pg\_database

The catalog `pg_database` stores information about the available databases. Databases are created with the [CREATE DATABASE](#) command. Consult [Chapter 22](#) for details about the meaning of some of the parameters.

Unlike most system catalogs, `pg_database` is shared across all databases of a cluster: there is only one copy of `pg_database` per cluster, not one per database.

**Table 54.15. pg\_database Columns**

| Column Type               | Description    |
|---------------------------|----------------|
| <code>oid oid</code>      | Row identifier |
| <code>datname name</code> |                |

| Column Type                                                                  | Description                                                                                                                                                                                                                                                                                                              |
|------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                                                              | Database name                                                                                                                                                                                                                                                                                                            |
| <code>datdba oid</code> (references <code>pg_authid .oid</code> )            | Owner of the database, usually the user who created it                                                                                                                                                                                                                                                                   |
| <code>encoding int4</code>                                                   | Character encoding for this database ( <code>pg_encoding_to_char()</code> can translate this number to the encoding name)                                                                                                                                                                                                |
| <code>datcollate name</code>                                                 | LC_COLLATE for this database                                                                                                                                                                                                                                                                                             |
| <code>datctype name</code>                                                   | LC_CTYPE for this database                                                                                                                                                                                                                                                                                               |
| <code>datistemplate bool</code>                                              | If true, then this database can be cloned by any user with <code>CREATEDB</code> privileges; if false, then only superusers or the owner of the database can clone it.                                                                                                                                                   |
| <code>datallowconn bool</code>                                               | If false then no one can connect to this database. This is used to protect the <code>template0</code> database from being altered.                                                                                                                                                                                       |
| <code>dathasloginevt bool</code>                                             | Indicates that there are login event triggers defined for this database. This flag is used to avoid extra lookups on the <code>pg_event_trigger</code> table during each backend startup. This flag is used internally by Postgres Pro and should not be manually altered or read for monitoring purposes.               |
| <code>datconndefault int4</code>                                             | Sets maximum number of concurrent connections that can be made to this database. -1 means no limit, -2 indicates the database is invalid.                                                                                                                                                                                |
| <code>datlastsysoid oid</code>                                               | Last system OID in the database; useful particularly to <code>pg_dump</code>                                                                                                                                                                                                                                             |
| <code>datfrozenxid xid</code>                                                | All transaction IDs before this one have been replaced with a permanent (“frozen”) transaction ID in this database. This is used to track whether the database needs to be vacuumed in order to allow <code>pg_xact</code> to be shrunk. It is the minimum of the per-table <code>pg_class .rel-frozenxid</code> values. |
| <code>datminmxid xid</code>                                                  | All multixact IDs before this one have been replaced with a transaction ID in this database. This is used to track whether the database needs to be vacuumed in order to allow <code>pg_multixact</code> to be shrunk. It is the minimum of the per-table <code>pg_class .relminmxid</code> values.                      |
| <code>dattablespace oid</code> (references <code>pg_tablespace .oid</code> ) | The default tablespace for the database. Within this database, all tables for which <code>pg_class .reltablespace</code> is zero will be stored in this tablespace; in particular, all the non-shared system catalogs will be there.                                                                                     |
| <code>datacl aclitem[]</code>                                                | Access privileges; see <a href="#">Section 5.7</a> for details                                                                                                                                                                                                                                                           |

## 54.16. pg\_db\_role\_setting

The catalog `pg_db_role_setting` records the default values that have been set for run-time configuration variables, for each role and database combination.

Unlike most system catalogs, `pg_db_role_setting` is shared across all databases of a cluster: there is only one copy of `pg_db_role_setting` per cluster, not one per database.

**Table 54.16. pg\_db\_role\_setting Columns**

| Column Type                                                   | Description                                                                            |
|---------------------------------------------------------------|----------------------------------------------------------------------------------------|
| setdatabase oid (references <a href="#">pg_database</a> .oid) | The OID of the database the setting is applicable to, or zero if not database-specific |
| setrole oid (references <a href="#">pg_authid</a> .oid)       | The OID of the role the setting is applicable to, or zero if not role-specific         |
| setconfig text[]                                              | Defaults for run-time configuration variables                                          |

## 54.17. pg\_default\_acl

The catalog `pg_default_acl` stores initial privileges to be assigned to newly created objects.

**Table 54.17. pg\_default\_acl Columns**

| Column Type                                                        | Description                                                                                                                                                                     |
|--------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| oid oid                                                            | Row identifier                                                                                                                                                                  |
| defaclrole oid (references <a href="#">pg_authid</a> .oid)         | The OID of the role associated with this entry                                                                                                                                  |
| defaclnamespace oid (references <a href="#">pg_namespace</a> .oid) | The OID of the namespace associated with this entry, or zero if none                                                                                                            |
| defaclobjtype char                                                 | Type of object this entry is for: <code>r</code> = relation (table, view), <code>s</code> = sequence, <code>f</code> = function, <code>T</code> = type, <code>n</code> = schema |
| defaclacl aclitem[]                                                | Access privileges that this type of object should have on creation                                                                                                              |

A `pg_default_acl` entry shows the initial privileges to be assigned to an object belonging to the indicated user. There are currently two types of entry: “global” entries with `defaclnamespace` = zero, and “per-schema” entries that reference a particular schema. If a global entry is present then it *overrides* the normal hard-wired default privileges for the object type. A per-schema entry, if present, represents privileges to be *added to* the global or hard-wired default privileges.

Note that when an ACL entry in another catalog is null, it is taken to represent the hard-wired default privileges for its object, *not* whatever might be in `pg_default_acl` at the moment. `pg_default_acl` is only consulted during object creation.

## 54.18. pg\_depend

The catalog `pg_depend` records the dependency relationships between database objects. This information allows `DROP` commands to find which other objects must be dropped by `DROP CASCADE` or prevent dropping in the `DROP RESTRICT` case.

See also [pg\\_shdepend](#), which performs a similar function for dependencies involving objects that are shared across a database cluster.

**Table 54.18. pg\_depend Columns**

| Column Type                                            | Description                                                                                               |
|--------------------------------------------------------|-----------------------------------------------------------------------------------------------------------|
| classid oid (references <a href="#">pg_class</a> .oid) | The OID of the system catalog the dependent object is in, or zero for a <code>DEPENDENCY_PIN</code> entry |

| Column Type                                                         | Description                                                                                                                                                                       |
|---------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>objid oid</code> (references any OID column)                  | The OID of the specific dependent object, or zero for a <code>DEPENDENCY_PIN</code> entry                                                                                         |
| <code>objsubid int4</code>                                          | For a table column, this is the column number (the <code>objid</code> and <code>classid</code> refer to the table itself). For all other object types, this column is zero.       |
| <code>refclassid oid</code> (references <code>pg_class.oid</code> ) | The OID of the system catalog the referenced object is in                                                                                                                         |
| <code>refobjid oid</code> (references any OID column)               | The OID of the specific referenced object                                                                                                                                         |
| <code>refobjsubid int4</code>                                       | For a table column, this is the column number (the <code>refobjid</code> and <code>refclassid</code> refer to the table itself). For all other object types, this column is zero. |
| <code>deptype char</code>                                           | A code defining the specific semantics of this dependency relationship; see text                                                                                                  |

In all cases, a `pg_depend` entry indicates that the referenced object cannot be dropped without also dropping the dependent object. However, there are several subflavors identified by `deptype`:

#### `DEPENDENCY_NORMAL` (n)

A normal relationship between separately-created objects. The dependent object can be dropped without affecting the referenced object. The referenced object can only be dropped by specifying `CASCADE`, in which case the dependent object is dropped, too. Example: a table column has a normal dependency on its data type.

#### `DEPENDENCY_AUTO` (a)

The dependent object can be dropped separately from the referenced object, and should be automatically dropped (regardless of `RESTRICT` or `CASCADE` mode) if the referenced object is dropped. Example: a named constraint on a table is made auto-dependent on the table, so that it will go away if the table is dropped.

#### `DEPENDENCY_INTERNAL` (i)

The dependent object was created as part of creation of the referenced object, and is really just a part of its internal implementation. A direct `DROP` of the dependent object will be disallowed outright (we'll tell the user to issue a `DROP` against the referenced object, instead). A `DROP` of the referenced object will result in automatically dropping the dependent object whether `CASCADE` is specified or not. If the dependent object has to be dropped due to a dependency on some other object being removed, its drop is converted to a drop of the referenced object, so that `NORMAL` and `AUTO` dependencies of the dependent object behave much like they were dependencies of the referenced object. Example: a view's `ON SELECT` rule is made internally dependent on the view, preventing it from being dropped while the view remains. Dependencies of the rule (such as tables it refers to) act as if they were dependencies of the view.

#### `DEPENDENCY_PARTITION_PRI` (P)

#### `DEPENDENCY_PARTITION_SEC` (S)

The dependent object was created as part of creation of the referenced object, and is really just a part of its internal implementation; however, unlike `INTERNAL`, there is more than one such referenced object. The dependent object must not be dropped unless at least one of these referenced objects is dropped; if any one is, the dependent object should be dropped whether or not `CASCADE` is specified. Also unlike `INTERNAL`, a drop of some other object that the dependent object depends on does not result in automatic deletion of any partition-referenced object. Hence, if the drop does not cascade to at least one of these objects via some other path, it will be refused. (In most cases, the dependent object shares all its non-partition dependencies with at least one partition-referenced object, so that this restriction does not result in blocking any cascaded delete.) Primary and secondary partition

dependencies behave identically except that the primary dependency is preferred for use in error messages; hence, a partition-dependent object should have one primary partition dependency and one or more secondary partition dependencies. Note that partition dependencies are made in addition to, not instead of, any dependencies the object would normally have. This simplifies `ATTACH/DETACH PARTITION` operations: the partition dependencies need only be added or removed. Example: a child partitioned index is made partition-dependent on both the partition table it is on and the parent partitioned index, so that it goes away if either of those is dropped, but not otherwise. The dependency on the parent index is primary, so that if the user tries to drop the child partitioned index, the error message will suggest dropping the parent index instead (not the table).

#### `DEPENDENCY_EXTENSION (e)`

The dependent object is a member of the *extension* that is the referenced object (see `pg_extension`). The dependent object can be dropped only via `DROP EXTENSION` on the referenced object. Functionally this dependency type acts the same as an `INTERNAL` dependency, but it's kept separate for clarity and to simplify `pg_dump`.

#### `DEPENDENCY_AUTO_EXTENSION (x)`

The dependent object is not a member of the extension that is the referenced object (and so it should not be ignored by `pg_dump`), but it cannot function without the extension and should be auto-dropped if the extension is. The dependent object may be dropped on its own as well. Functionally this dependency type acts the same as an `AUTO` dependency, but it's kept separate for clarity and to simplify `pg_dump`.

#### `DEPENDENCY_PIN (p)`

There is no dependent object; this type of entry is a signal that the system itself depends on the referenced object, and so that object must never be deleted. Entries of this type are created only by `initdb`. The columns for the dependent object contain zeroes.

Other dependency flavors might be needed in future.

Note that it's quite possible for two objects to be linked by more than one `pg_depend` entry. For example, a child partitioned index would have both a partition-type dependency on its associated partition table, and an auto dependency on each column of that table that it indexes. This sort of situation expresses the union of multiple dependency semantics. A dependent object can be dropped without `CASCADE` if any of its dependencies satisfies its condition for automatic dropping. Conversely, all the dependencies' restrictions about which objects must be dropped together must be satisfied.

## 54.19. `pg_description`

The catalog `pg_description` stores optional descriptions (comments) for each database object. Descriptions can be manipulated with the `COMMENT` command and viewed with `psql`'s `\d` commands. Descriptions of many built-in system objects are provided in the initial contents of `pg_description`.

See also `pg_shdescription`, which performs a similar function for descriptions involving objects that are shared across a database cluster.

**Table 54.19. `pg_description` Columns**

| Column Type                                                       | Description                                                                                                                                                                                |
|-------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>objoid oid</code> (references any OID column)               | The OID of the object this description pertains to                                                                                                                                         |
| <code>classoid oid</code> (references <code>pg_class.oid</code> ) | The OID of the system catalog this object appears in                                                                                                                                       |
| <code>objsubid int4</code>                                        | For a comment on a table column, this is the column number (the <code>objoid</code> and <code>classoid</code> refer to the table itself). For all other object types, this column is zero. |
| <code>description text</code>                                     |                                                                                                                                                                                            |

| Column Type | Description                                                  |
|-------------|--------------------------------------------------------------|
|             | Arbitrary text that serves as the description of this object |

## 54.20. pg\_enum

The `pg_enum` catalog contains entries showing the values and labels for each enum type. The internal representation of a given enum value is actually the OID of its associated row in `pg_enum`.

**Table 54.20. pg\_enum Columns**

| Column Type                                          | Description                                                      |
|------------------------------------------------------|------------------------------------------------------------------|
| oid oid                                              | Row identifier                                                   |
| enumtypid oid (references <code>pg_type</code> .oid) | The OID of the <code>pg_type</code> entry owning this enum value |
| enumsortorder float4                                 | The sort position of this enum value within its enum type        |
| enumlabel name                                       | The textual label for this enum value                            |

The OIDs for `pg_enum` rows follow a special rule: even-numbered OIDs are guaranteed to be ordered in the same way as the sort ordering of their enum type. That is, if two even OIDs belong to the same enum type, the smaller OID must have the smaller `enumsortorder` value. Odd-numbered OID values need bear no relationship to the sort order. This rule allows the enum comparison routines to avoid catalog lookups in many common cases. The routines that create and alter enum types attempt to assign even OIDs to enum values whenever possible.

When an enum type is created, its members are assigned sort-order positions 1..*n*. But members added later might be given negative or fractional values of `enumsortorder`. The only requirement on these values is that they be correctly ordered and unique within each enum type.

## 54.21. pg\_event\_trigger

The catalog `pg_event_trigger` stores event triggers. See [Chapter 42](#) for more information.

**Table 54.21. pg\_event\_trigger Columns**

| Column Type                                           | Description                                                                                                                                                                                                                        |
|-------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| oid oid                                               | Row identifier                                                                                                                                                                                                                     |
| evtname name                                          | Trigger name (must be unique)                                                                                                                                                                                                      |
| evtevent name                                         | Identifies the event for which this trigger fires                                                                                                                                                                                  |
| evtowner oid (references <code>pg_authid</code> .oid) | Owner of the event trigger                                                                                                                                                                                                         |
| evtfoid oid (references <code>pg_proc</code> .oid)    | The function to be called                                                                                                                                                                                                          |
| evtenabled char                                       | Controls in which <a href="#">session_replication_role</a> modes the event trigger fires. O = trigger fires in “origin” and “local” modes, D = trigger is disabled, R = trigger fires in “replica” mode, A = trigger fires always. |

| Column Type    | Description                                                                                                                           |
|----------------|---------------------------------------------------------------------------------------------------------------------------------------|
| evttags text[] | Command tags for which this trigger will fire. If NULL, the firing of this trigger is not restricted on the basis of the command tag. |

## 54.22. pg\_extension

The catalog `pg_extension` stores information about the installed extensions. See [Section 40.17](#) for details about extensions.

**Table 54.22. `pg_extension` Columns**

| Column Type                                                  | Description                                                                                         |
|--------------------------------------------------------------|-----------------------------------------------------------------------------------------------------|
| oid oid                                                      | Row identifier                                                                                      |
| extname name                                                 | Name of the extension                                                                               |
| extowner oid (references <code>pg_authid</code> .oid)        | Owner of the extension                                                                              |
| extnamespace oid (references <code>pg_namespace</code> .oid) | Schema containing the extension's exported objects                                                  |
| extrelocatable bool                                          | True if extension can be relocated to another schema                                                |
| extversion text                                              | Version name for the extension                                                                      |
| extconfig oid[] (references <code>pg_class</code> .oid)      | Array of <code>regclass</code> OIDs for the extension's configuration table(s), or NULL if none     |
| extcondition text[]                                          | Array of WHERE-clause filter conditions for the extension's configuration table(s), or NULL if none |

Note that unlike most catalogs with a “namespace” column, `extnamespace` is not meant to imply that the extension belongs to that schema. Extension names are never schema-qualified. Rather, `extnamespace` indicates the schema that contains most or all of the extension's objects. If `extrelocatable` is true, then this schema must in fact contain all schema-qualifiable objects belonging to the extension.

## 54.23. pg\_foreign\_data\_wrapper

The catalog `pg_foreign_data_wrapper` stores foreign-data wrapper definitions. A foreign-data wrapper is the mechanism by which external data, residing on foreign servers, is accessed.

**Table 54.23. `pg_foreign_data_wrapper` Columns**

| Column Type                                           | Description                       |
|-------------------------------------------------------|-----------------------------------|
| oid oid                                               | Row identifier                    |
| fdwname name                                          | Name of the foreign-data wrapper  |
| fdwowner oid (references <code>pg_authid</code> .oid) | Owner of the foreign-data wrapper |

| Column Type                                                           | Description                                                                                                                                                                                                                                               |
|-----------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>fdwhandler oid</code> (references <code>pg_proc .oid</code> )   | References a handler function that is responsible for supplying execution routines for the foreign-data wrapper. Zero if no handler is provided                                                                                                           |
| <code>fdwvalidator oid</code> (references <code>pg_proc .oid</code> ) | References a validator function that is responsible for checking the validity of the options given to the foreign-data wrapper, as well as options for foreign servers and user mappings using the foreign-data wrapper. Zero if no validator is provided |
| <code>fdwacl aclitem[]</code>                                         | Access privileges; see <a href="#">Section 5.7</a> for details                                                                                                                                                                                            |
| <code>fdwoptions text[]</code>                                        | Foreign-data wrapper specific options, as “keyword=value” strings                                                                                                                                                                                         |

## 54.24. `pg_foreign_server`

The catalog `pg_foreign_server` stores foreign server definitions. A foreign server describes a source of external data, such as a remote server. Foreign servers are accessed via foreign-data wrappers.

**Table 54.24. `pg_foreign_server` Columns**

| Column Type                                                                     | Description                                                    |
|---------------------------------------------------------------------------------|----------------------------------------------------------------|
| <code>oid oid</code>                                                            | Row identifier                                                 |
| <code>srvname name</code>                                                       | Name of the foreign server                                     |
| <code>srvowner oid</code> (references <code>pg_authid .oid</code> )             | Owner of the foreign server                                    |
| <code>srvfdw oid</code> (references <code>pg_foreign_data_wrapper .oid</code> ) | OID of the foreign-data wrapper of this foreign server         |
| <code>srvtype text</code>                                                       | Type of the server (optional)                                  |
| <code>srvversion text</code>                                                    | Version of the server (optional)                               |
| <code>srvacl aclitem[]</code>                                                   | Access privileges; see <a href="#">Section 5.7</a> for details |
| <code>srvoptions text[]</code>                                                  | Foreign server specific options, as “keyword=value” strings    |

## 54.25. `pg_foreign_table`

The catalog `pg_foreign_table` contains auxiliary information about foreign tables. A foreign table is primarily represented by a `pg_class` entry, just like a regular table. Its `pg_foreign_table` entry contains the information that is pertinent only to foreign tables and not any other kind of relation.

**Table 54.25. `pg_foreign_table` Columns**

| Column Type                                                                 | Description                                                       |
|-----------------------------------------------------------------------------|-------------------------------------------------------------------|
| <code>ftrelid oid</code> (references <code>pg_class .oid</code> )           | The OID of the <code>pg_class</code> entry for this foreign table |
| <code>ftserver oid</code> (references <code>pg_foreign_server .oid</code> ) |                                                                   |

| Column Type                   | Description                                       |
|-------------------------------|---------------------------------------------------|
|                               | OID of the foreign server for this foreign table  |
| <code>ftoptions text[]</code> | Foreign table options, as “keyword=value” strings |

## 54.26. `pg_index`

The catalog `pg_index` contains part of the information about indexes. The rest is mostly in `pg_class`.

**Table 54.26. `pg_index` Columns**

| Column Type                                                          | Description                                                                                                                                                                                                                                                                            |
|----------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>indexrelid oid</code> (references <code>pg_class .oid</code> ) | The OID of the <code>pg_class</code> entry for this index                                                                                                                                                                                                                              |
| <code>indrelid oid</code> (references <code>pg_class .oid</code> )   | The OID of the <code>pg_class</code> entry for the table this index is for                                                                                                                                                                                                             |
| <code>indnatts int2</code>                                           | The total number of columns in the index (duplicates <code>pg_class.relnatts</code> ); this number includes both key and included attributes                                                                                                                                           |
| <code>indnkeyatts int2</code>                                        | The number of <i>key columns</i> in the index, not counting any <i>included columns</i> , which are merely stored and do not participate in the index semantics                                                                                                                        |
| <code>indisunique bool</code>                                        | If true, this is a unique index                                                                                                                                                                                                                                                        |
| <code>indisprimary bool</code>                                       | If true, this index represents the primary key of the table ( <code>indisunique</code> should always be true when this is true)                                                                                                                                                        |
| <code>indisexclusion bool</code>                                     | If true, this index supports an exclusion constraint                                                                                                                                                                                                                                   |
| <code>indimmediate bool</code>                                       | If true, the uniqueness check is enforced immediately on insertion (irrelevant if <code>indisunique</code> is not true)                                                                                                                                                                |
| <code>indisclustered bool</code>                                     | If true, the table was last clustered on this index                                                                                                                                                                                                                                    |
| <code>indisvalid bool</code>                                         | If true, the index is currently valid for queries. False means the index is possibly incomplete: it must still be modified by <code>INSERT/UPDATE</code> operations, but it cannot safely be used for queries. If it is unique, the uniqueness property is not guaranteed true either. |
| <code>indcheckxmin bool</code>                                       | If true, queries must not use the index until the <code>xmin</code> of this <code>pg_index</code> row is below their <code>TransactionXmin</code> event horizon, because the table may contain broken <code>HOT chains</code> with incompatible rows that they can see                 |
| <code>indisready bool</code>                                         | If true, the index is currently ready for inserts. False means the index must be ignored by <code>INSERT/UPDATE</code> operations.                                                                                                                                                     |
| <code>indislive bool</code>                                          | If false, the index is in process of being dropped, and should be ignored for all purposes (including <code>HOT-safety</code> decisions)                                                                                                                                               |
| <code>indisreplident bool</code>                                     |                                                                                                                                                                                                                                                                                        |

| Column Type                                                                                                | Description                                                                                                                                                                                                                                                                                                                                                                                                                  |
|------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                                                                                            | If true this index has been chosen as “replica identity” using <code>ALTER TABLE ... REPLICA IDENTITY USING INDEX ...</code> .                                                                                                                                                                                                                                                                                               |
| <code>indkey</code> <code>int2vector</code> (references <code>pg_attribute</code> <code>.attnum</code> )   | This is an array of <code>indnatts</code> values that indicate which table columns this index indexes. For example a value of 1 3 would mean that the first and the third table columns make up the index entries. Key columns come before non-key (included) columns. A zero in this array indicates that the corresponding index attribute is an expression over the table columns, rather than a simple column reference. |
| <code>indcollation</code> <code>oidvector</code> (references <code>pg_collation</code> <code>.oid</code> ) | For each column in the index key ( <code>indnkeyatts</code> values), this contains the OID of the collation to use for the index, or zero if the column is not of a collatable data type.                                                                                                                                                                                                                                    |
| <code>indclass</code> <code>oidvector</code> (references <code>pg_opclass</code> <code>.oid</code> )       | For each column in the index key ( <code>indnkeyatts</code> values), this contains the OID of the operator class to use. See <code>pg_opclass</code> for details.                                                                                                                                                                                                                                                            |
| <code>indoption</code> <code>int2vector</code>                                                             | This is an array of <code>indnkeyatts</code> values that store per-column flag bits. The meaning of the bits is defined by the index's access method.                                                                                                                                                                                                                                                                        |
| <code>indexprs</code> <code>pg_node_tree</code>                                                            | Expression trees (in <code>nodeToString()</code> representation) for index attributes that are not simple column references. This is a list with one element for each zero entry in <code>indkey</code> . Null if all index attributes are simple references.                                                                                                                                                                |
| <code>indpred</code> <code>pg_node_tree</code>                                                             | Expression tree (in <code>nodeToString()</code> representation) for partial index predicate. Null if not a partial index.                                                                                                                                                                                                                                                                                                    |

## 54.27. `pg_inherits`

The catalog `pg_inherits` records information about table and index inheritance hierarchies. There is one entry for each direct parent-child table or index relationship in the database. (Indirect inheritance can be determined by following chains of entries.)

**Table 54.27. `pg_inherits` Columns**

| Column Type                                                                                   | Description                                                                                                                                                                                                                                                                                        |
|-----------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>inhrelid</code> <code>oid</code> (references <code>pg_class</code> <code>.oid</code> )  | The OID of the child table or index                                                                                                                                                                                                                                                                |
| <code>inhparent</code> <code>oid</code> (references <code>pg_class</code> <code>.oid</code> ) | The OID of the parent table or index                                                                                                                                                                                                                                                               |
| <code>inhseqno</code> <code>int4</code>                                                       | If there is more than one direct parent for a child table (multiple inheritance), this number tells the order in which the inherited columns are to be arranged. The count starts at 1. Indexes cannot have multiple inheritance, since they can only inherit when using declarative partitioning. |
| <code>inhdetachpending</code> <code>bool</code>                                               | <code>true</code> for a partition that is in the process of being detached; <code>false</code> otherwise.                                                                                                                                                                                          |

## 54.28. `pg_init_privs`

The catalog `pg_init_privs` records information about the initial privileges of objects in the system. There is one entry for each object in the database which has a non-default (non-NULL) initial set of privileges.

Objects can have initial privileges either by having those privileges set when the system is initialized (by `initdb`) or when the object is created during a `CREATE EXTENSION` and the extension script sets initial privileges using the `GRANT` system. Note that the system will automatically handle recording of the privileges during the extension script and that extension authors need only use the `GRANT` and `REVOKE` statements in their script to have the privileges recorded. The `privtype` column indicates if the initial privilege was set by `initdb` or during a `CREATE EXTENSION` command.

Objects which have initial privileges set by `initdb` will have entries where `privtype` is 'i', while objects which have initial privileges set by `CREATE EXTENSION` will have entries where `privtype` is 'e'.

**Table 54.28. `pg_init_privs` Columns**

| Column Type                                                        | Description                                                                                                                                                                   |
|--------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>objoid oid</code> (references any OID column)                | The OID of the specific object                                                                                                                                                |
| <code>classoid oid</code> (references <code>pg_class .oid</code> ) | The OID of the system catalog the object is in                                                                                                                                |
| <code>objsubid int4</code>                                         | For a table column, this is the column number (the <code>objoid</code> and <code>classoid</code> refer to the table itself). For all other object types, this column is zero. |
| <code>privtype char</code>                                         | A code defining the type of initial privilege of this object; see text                                                                                                        |
| <code>initprivs aclitem[]</code>                                   | The initial access privileges; see <a href="#">Section 5.7</a> for details                                                                                                    |

## 54.29. `pg_language`

The catalog `pg_language` registers languages in which you can write functions or stored procedures. See [CREATE LANGUAGE](#) and [Chapter 44](#) for more information about language handlers.

**Table 54.29. `pg_language` Columns**

| Column Type                                                            | Description                                                                                                                                                                                                                                                |
|------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>oid oid</code>                                                   | Row identifier                                                                                                                                                                                                                                             |
| <code>lanname name</code>                                              | Name of the language                                                                                                                                                                                                                                       |
| <code>lanowner oid</code> (references <code>pg_authid .oid</code> )    | Owner of the language                                                                                                                                                                                                                                      |
| <code>lanispl bool</code>                                              | This is false for internal languages (such as SQL) and true for user-defined languages. Currently, <code>pg_dump</code> still uses this to determine which languages need to be dumped, but this might be replaced by a different mechanism in the future. |
| <code>lanpltrusted bool</code>                                         | True if this is a trusted language, which means that it is believed not to grant access to anything outside the normal SQL execution environment. Only superusers can create functions in untrusted languages.                                             |
| <code>lanplcallfoid oid</code> (references <code>pg_proc .oid</code> ) | For noninternal languages this references the language handler, which is a special function that is responsible for executing all functions that are written in the particular language. Zero for internal languages.                                      |
| <code>laninline oid</code> (references <code>pg_proc .oid</code> )     |                                                                                                                                                                                                                                                            |

| Column Type                                                             | Description                                                                                                                                                                      |
|-------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                                                         | This references a function that is responsible for executing “inline” anonymous code blocks ( <a href="#">DO</a> blocks). Zero if inline blocks are not supported.               |
| <code>lanvalidator oid</code> (references <a href="#">pg_proc</a> .oid) | This references a language validator function that is responsible for checking the syntax and validity of new functions when they are created. Zero if no validator is provided. |
| <code>lanacl aclitem[]</code>                                           | Access privileges; see <a href="#">Section 5.7</a> for details                                                                                                                   |

## 54.30. pg\_largeobject

The catalog `pg_largeobject` holds the data making up “large objects”. A large object is identified by an OID assigned when it is created. Each large object is broken into segments or “pages” small enough to be conveniently stored as rows in `pg_largeobject`. The amount of data per page is defined to be `LOBLKSIZE` (which is currently `BLCKSZ/4`, or typically 2 kB).

Prior to PostgreSQL 9.0, there was no permission structure associated with large objects. As a result, `pg_largeobject` was publicly readable and could be used to obtain the OIDs (and contents) of all large objects in the system. This is no longer the case; use [pg\\_largeobject\\_metadata](#) to obtain a list of large object OIDs.

**Table 54.30. pg\_largeobject Columns**

| Column Type                                                                     | Description                                                                                                          |
|---------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------|
| <code>loid oid</code> (references <a href="#">pg_largeobject_metadata</a> .oid) | Identifier of the large object that includes this page                                                               |
| <code>pageno int4</code>                                                        | Page number of this page within its large object (counting from zero)                                                |
| <code>data bytea</code>                                                         | Actual data stored in the large object. This will never be more than <code>LOBLKSIZE</code> bytes and might be less. |

Each row of `pg_largeobject` holds data for one page of a large object, beginning at byte offset (`pageno * LOBLKSIZE`) within the object. The implementation allows sparse storage: pages might be missing, and might be shorter than `LOBLKSIZE` bytes even if they are not the last page of the object. Missing regions within a large object read as zeroes.

## 54.31. pg\_largeobject\_metadata

The catalog `pg_largeobject_metadata` holds metadata associated with large objects. The actual large object data is stored in [pg\\_largeobject](#).

**Table 54.31. pg\_largeobject\_metadata Columns**

| Column Type                                                           | Description               |
|-----------------------------------------------------------------------|---------------------------|
| <code>oid oid</code>                                                  | Row identifier            |
| <code>lomowner oid</code> (references <a href="#">pg_authid</a> .oid) | Owner of the large object |
| <code>lomacl aclitem[]</code>                                         |                           |

| Column Type | Description                                                    |
|-------------|----------------------------------------------------------------|
|             | Access privileges; see <a href="#">Section 5.7</a> for details |

## 54.32. pg\_namespace

The catalog `pg_namespace` stores namespaces. A namespace is the structure underlying SQL schemas: each namespace can have a separate collection of relations, types, etc. without name conflicts.

**Table 54.32. pg\_namespace Columns**

| Column Type                                              | Description                                                    |
|----------------------------------------------------------|----------------------------------------------------------------|
| oid oid                                                  | Row identifier                                                 |
| nspname name                                             | Name of the namespace                                          |
| nspowner oid (references <a href="#">pg_authid</a> .oid) | Owner of the namespace                                         |
| nspacl aclitem[]                                         | Access privileges; see <a href="#">Section 5.7</a> for details |

## 54.33. pg\_opclass

The catalog `pg_opclass` defines index access method operator classes. Each operator class defines semantics for index columns of a particular data type and a particular index access method. An operator class essentially specifies that a particular operator family is applicable to a particular indexable column data type. The set of operators from the family that are actually usable with the indexed column are whichever ones accept the column's data type as their left-hand input.

Operator classes are described at length in [Section 40.16](#).

**Table 54.33. pg\_opclass Columns**

| Column Type                                                     | Description                                                           |
|-----------------------------------------------------------------|-----------------------------------------------------------------------|
| oid oid                                                         | Row identifier                                                        |
| opcmethod oid (references <a href="#">pg_am</a> .oid)           | Index access method operator class is for                             |
| opcname name                                                    | Name of this operator class                                           |
| opcnamespace oid (references <a href="#">pg_namespace</a> .oid) | Namespace of this operator class                                      |
| opcowner oid (references <a href="#">pg_authid</a> .oid)        | Owner of the operator class                                           |
| opcfamily oid (references <a href="#">pg_opfamily</a> .oid)     | Operator family containing the operator class                         |
| opcintype oid (references <a href="#">pg_type</a> .oid)         | Data type that the operator class indexes                             |
| opcdefault bool                                                 | True if this operator class is the default for <code>opcintype</code> |
| opckeytype oid (references <a href="#">pg_type</a> .oid)        |                                                                       |

| Column Type | Description                                                             |
|-------------|-------------------------------------------------------------------------|
|             | Type of data stored in index, or zero if same as <code>opcintype</code> |

An operator class's `opcmethod` must match the `opfmethod` of its containing operator family. Also, there must be no more than one `pg_opclass` row having `opcdefault` true for any given combination of `opcmethod` and `opcintype`.

## 54.34. pg\_operator

The catalog `pg_operator` stores information about operators. See [CREATE OPERATOR](#) and [Section 40.14](#) for more information.

**Table 54.34. pg\_operator Columns**

| Column Type                                                                                            | Description                                                                          |
|--------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------|
| <code>oid oid</code>                                                                                   | Row identifier                                                                       |
| <code>oprname name</code>                                                                              | Name of the operator                                                                 |
| <code>oprnamespace oid (references <a href="#">pg_namespace</a> .oid)</code>                           | The OID of the namespace that contains this operator                                 |
| <code>oprowner oid (references <a href="#">pg_authid</a> .oid)</code>                                  | Owner of the operator                                                                |
| <code>oprkind char</code><br><code>b = infix operator ("both"), or l = prefix operator ("left")</code> |                                                                                      |
| <code>oprcanmerge bool</code>                                                                          | This operator supports merge joins                                                   |
| <code>oprcanhash bool</code>                                                                           | This operator supports hash joins                                                    |
| <code>oprleft oid (references <a href="#">pg_type</a> .oid)</code>                                     | Type of the left operand (zero for a prefix operator)                                |
| <code>oprright oid (references <a href="#">pg_type</a> .oid)</code>                                    | Type of the right operand                                                            |
| <code>oprresult oid (references <a href="#">pg_type</a> .oid)</code>                                   | Type of the result (zero for a not-yet-defined "shell" operator)                     |
| <code>oprcom oid (references <a href="#">pg_operator</a> .oid)</code>                                  | Commutator of this operator (zero if none)                                           |
| <code>oprnegate oid (references <a href="#">pg_operator</a> .oid)</code>                               | Negator of this operator (zero if none)                                              |
| <code>oprcode regproc (references <a href="#">pg_proc</a> .oid)</code>                                 | Function that implements this operator (zero for a not-yet-defined "shell" operator) |
| <code>oprrest regproc (references <a href="#">pg_proc</a> .oid)</code>                                 | Restriction selectivity estimation function for this operator (zero if none)         |
| <code>oprjoin regproc (references <a href="#">pg_proc</a> .oid)</code>                                 | Join selectivity estimation function for this operator (zero if none)                |

## 54.35. pg\_opfamily

The catalog `pg_opfamily` defines operator families. Each operator family is a collection of operators and associated support routines that implement the semantics specified for a particular index access

method. Furthermore, the operators in a family are all “compatible”, in a way that is specified by the access method. The operator family concept allows cross-data-type operators to be used with indexes and to be reasoned about using knowledge of access method semantics.

Operator families are described at length in [Section 40.16](#).

**Table 54.35. `pg_opfamily` Columns**

| Column Type                                                                  | Description                                |
|------------------------------------------------------------------------------|--------------------------------------------|
| <code>oid oid</code>                                                         | Row identifier                             |
| <code>opfmeth oid (references <a href="#">pg_am</a> .oid)</code>             | Index access method operator family is for |
| <code>opfname name</code>                                                    | Name of this operator family               |
| <code>opfnamespace oid (references <a href="#">pg_namespace</a> .oid)</code> | Namespace of this operator family          |
| <code>opfowner oid (references <a href="#">pg_authid</a> .oid)</code>        | Owner of the operator family               |

The majority of the information defining an operator family is not in its `pg_opfamily` row, but in the associated rows in [pg\\_amop](#), [pg\\_amproc](#), and [pg\\_opclass](#).

## 54.36. `pg_partitioned_table`

The catalog `pg_partitioned_table` stores information about how tables are partitioned.

**Table 54.36. `pg_partitioned_table` Columns**

| Column Type                                                                         | Description                                                                                                                                                                                                                                                                                                                                                                      |
|-------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>partrelid oid (references <a href="#">pg_class</a> .oid)</code>               | The OID of the <a href="#">pg_class</a> entry for this partitioned table                                                                                                                                                                                                                                                                                                         |
| <code>partstrat char</code>                                                         | Partitioning strategy; <code>h</code> = hash partitioned table, <code>l</code> = list partitioned table, <code>r</code> = range partitioned table                                                                                                                                                                                                                                |
| <code>partnatts int2</code>                                                         | The number of columns in the partition key                                                                                                                                                                                                                                                                                                                                       |
| <code>partdefid oid (references <a href="#">pg_class</a> .oid)</code>               | The OID of the <a href="#">pg_class</a> entry for the default partition of this partitioned table, or zero if this partitioned table does not have a default partition                                                                                                                                                                                                           |
| <code>partattrs int2vector (references <a href="#">pg_attribute</a> .attnum)</code> | This is an array of <code>partnatts</code> values that indicate which table columns are part of the partition key. For example, a value of <code>1 3</code> would mean that the first and the third table columns make up the partition key. A zero in this array indicates that the corresponding partition key column is an expression, rather than a simple column reference. |
| <code>partclass oidvector (references <a href="#">pg_opclass</a> .oid)</code>       | For each column in the partition key, this contains the OID of the operator class to use. See <a href="#">pg_opclass</a> for details.                                                                                                                                                                                                                                            |
| <code>partcollation oidvector (references <a href="#">pg_collation</a> .oid)</code> | For each column in the partition key, this contains the OID of the collation to use for partitioning, or zero if the column is not of a collatable data type.                                                                                                                                                                                                                    |

| Column Type            | Description                                                                                                                                                                                                                                                                |
|------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| partexprs pg_node_tree | Expression trees (in <code>nodeToString()</code> representation) for partition key columns that are not simple column references. This is a list with one element for each zero entry in <code>partattrs</code> . Null if all partition key columns are simple references. |

## 54.37. pg\_policy

The catalog `pg_policy` stores row-level security policies for tables. A policy includes the kind of command that it applies to (possibly all commands), the roles that it applies to, the expression to be added as a security-barrier qualification to queries that include the table, and the expression to be added as a `WITH CHECK` option for queries that attempt to add new records to the table.

**Table 54.37. pg\_policy Columns**

| Column Type                                             | Description                                                                                                                                                                                                                                    |
|---------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| oid oid                                                 | Row identifier                                                                                                                                                                                                                                 |
| polname name                                            | The name of the policy                                                                                                                                                                                                                         |
| polrelid oid (references <code>pg_class</code> .oid)    | The table to which the policy applies                                                                                                                                                                                                          |
| polcmd char                                             | The command type to which the policy is applied: <code>r</code> for <code>SELECT</code> , <code>a</code> for <code>INSERT</code> , <code>w</code> for <code>UPDATE</code> , <code>d</code> for <code>DELETE</code> , or <code>*</code> for all |
| polpermissive bool                                      | Is the policy permissive or restrictive?                                                                                                                                                                                                       |
| polroles oid[] (references <code>pg_authid</code> .oid) | The roles to which the policy is applied; zero means <code>PUBLIC</code> (and normally appears alone in the array)                                                                                                                             |
| polqual pg_node_tree                                    | The expression tree to be added to the security barrier qualifications for queries that use the table                                                                                                                                          |
| polwithcheck pg_node_tree                               | The expression tree to be added to the <code>WITH CHECK</code> qualifications for queries that attempt to add rows to the table                                                                                                                |

### Note

Policies stored in `pg_policy` are applied only when `pg_class.relrowsecurity` is set for their table.

## 54.38. pg\_proc

The catalog `pg_proc` stores information about functions, procedures, aggregate functions, and window functions (collectively also known as routines). See [CREATE FUNCTION](#), [CREATE PROCEDURE](#), and [Section 40.3](#) for more information.

If `prokind` indicates that the entry is for an aggregate function, there should be a matching row in `pg_aggregate`.

**Table 54.38. pg\_proc Columns**

| Column Type                                                     | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |

| prosecdef bool                                                  | Function is a security definer (i.e., a “setuid” function)                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| proleakproof bool                                               | The function has no side effects. No information about the arguments is conveyed except via the return value. Any function that might throw an error depending on the values of its arguments is not leak-proof.                                                                                                                                                                                                                                                                                                                                             |
| proisstrict bool                                                | Function returns null if any call argument is null. In that case the function won't actually be called at all. Functions that are not “strict” must be prepared to handle null inputs.                                                                                                                                                                                                                                                                                                                                                                       |
| proretset bool                                                  | Function returns a set (i.e., multiple values of the specified data type)                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| provolatile char                                                | <code>provolatile</code> tells whether the function's result depends only on its input arguments, or is affected by outside factors. It is <code>i</code> for “immutable” functions, which always deliver the same result for the same inputs. It is <code>s</code> for “stable” functions, whose results (for fixed inputs) do not change within a scan. It is <code>v</code> for “volatile” functions, whose results might change at any time. (Use <code>v</code> also for functions with side-effects, so that calls to them cannot get optimized away.) |
| proparallel char                                                | <code>proparallel</code> tells whether the function can be safely run in parallel mode. It is <code>s</code> for functions which are safe to run in parallel mode without restriction. It is <code>r</code> for functions which can be run in parallel mode, but their execution is restricted to the parallel group leader; parallel worker processes cannot invoke these functions. It is <code>u</code> for functions which are unsafe in parallel mode; the presence of such a function forces a serial execution plan.                                  |
| pronargs int2                                                   |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |

| Column Type                                                                  | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
|------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                                                              | Number of input arguments                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| <code>pronargdefaults int2</code>                                            | Number of arguments that have defaults                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| <code>prorettytype oid</code> (references <a href="#">pg_type</a> .oid)      | Data type of the return value                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| <code>proargtypes oidvector</code> (references <a href="#">pg_type</a> .oid) | An array of the data types of the function arguments. This includes only input arguments (including <code>INOUT</code> and <code>VARIADIC</code> arguments), and thus represents the call signature of the function.                                                                                                                                                                                                                                                                                   |
| <code>proallargtypes oid[]</code> (references <a href="#">pg_type</a> .oid)  | An array of the data types of the function arguments. This includes all arguments (including <code>OUT</code> and <code>INOUT</code> arguments); however, if all the arguments are <code>IN</code> arguments, this field will be null. Note that subscripting is 1-based, whereas for historical reasons <code>proargtypes</code> is subscripted from 0.                                                                                                                                               |
| <code>proargmodes char[]</code>                                              | An array of the modes of the function arguments, encoded as <code>i</code> for <code>IN</code> arguments, <code>o</code> for <code>OUT</code> arguments, <code>b</code> for <code>INOUT</code> arguments, <code>v</code> for <code>VARIADIC</code> arguments, <code>t</code> for <code>TABLE</code> arguments. If all the arguments are <code>IN</code> arguments, this field will be null. Note that subscripts correspond to positions of <code>proallargtypes</code> not <code>proargtypes</code> . |
| <code>proargnames text[]</code>                                              | An array of the names of the function arguments. Arguments without a name are set to empty strings in the array. If none of the arguments have a name, this field will be null. Note that subscripts correspond to positions of <code>proallargtypes</code> not <code>proargtypes</code> .                                                                                                                                                                                                             |
| <code>proargdefaults pg_node_tree</code>                                     | Expression trees (in <code>nodeToString()</code> representation) for default values. This is a list with <code>pronargdefaults</code> elements, corresponding to the last <i>N</i> input arguments (i.e., the last <i>N</i> <code>proargtypes</code> positions). If none of the arguments have defaults, this field will be null.                                                                                                                                                                      |
| <code>protrftypes oid[]</code> (references <a href="#">pg_type</a> .oid)     | An array of the argument/result data type(s) for which to apply transforms (from the function's <code>TRANSFORM</code> clause). Null if none.                                                                                                                                                                                                                                                                                                                                                          |
| <code>prosrc text</code>                                                     | This tells the function handler how to invoke the function. It might be the actual source code of the function for interpreted languages, a link symbol, a file name, or just about anything else, depending on the implementation language/call convention.                                                                                                                                                                                                                                           |
| <code>probin text</code>                                                     | Additional information about how to invoke the function. Again, the interpretation is language-specific.                                                                                                                                                                                                                                                                                                                                                                                               |
| <code>prosqlbody pg_node_tree</code>                                         | Pre-parsed SQL function body. This is used for SQL-language functions when the body is given in SQL-standard notation rather than as a string literal. It's null in other cases.                                                                                                                                                                                                                                                                                                                       |
| <code>proconfig text[]</code>                                                | Function's local settings for run-time configuration variables                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| <code>proacl aclitem[]</code>                                                | Access privileges; see <a href="#">Section 5.7</a> for details                                                                                                                                                                                                                                                                                                                                                                                                                                         |

For compiled functions, both built-in and dynamically loaded, `prosrc` contains the function's C-language name (link symbol). For SQL-language functions, `prosrc` contains the function's source text if that is specified as a string literal; but if the function body is specified in SQL-standard style, `prosrc` is unused (typically it's an empty string) and `prosqlbody` contains the pre-parsed definition. For all other current-

ly-known language types, `prosrc` contains the function's source text. `probin` is null except for dynamically-loaded C functions, for which it gives the name of the shared library file containing the function.

## 54.39. `pg_profile`

The catalog `pg_profile` lists all profiles available for your cluster. For details on profiles, see [CREATE PROFILE](#).

Profiles are cluster-wide, so `pg_profile` is shared across all databases of a cluster. This catalog is not publicly readable.

**Table 54.39. `pg_profile` Columns**

| Column Type                                                | Description                  |
|------------------------------------------------------------|------------------------------|
| oid oid                                                    | Row identifier               |
| pflname name                                               | Profile name                 |
| pflfailedloginattempts int4<br>FAILED_LOGIN_ATTEMPTS       | parameter value              |
| pflfailedauthkeepstime int4<br>FAILED_AUTH_KEEP_TIME       | parameter value (in seconds) |
| pfluserinactivetime int4<br>USER_INACTIVE_TIME             | parameter value (in seconds) |
| pflpasswordreusetime int4<br>PASSWORD_REUSE_TIME           | parameter value (in seconds) |
| pflpasswordreusemax int4<br>PASSWORD_REUSE_MAX             | parameter value              |
| pflpasswordlifetime int4<br>PASSWORD_LIFE_TIME             | parameter value (in seconds) |
| pflpasswordgracetime int4<br>PASSWORD_GRACE_TIME           | parameter value (in seconds) |
| pflpasswordminuniqchars int4<br>PASSWORD_MIN_UNIQUE_CHARS  | parameter value              |
| pflpasswordminlen int4<br>PASSWORD_MIN_LEN                 | parameter value              |
| pflpasswordrequirecomplex int4<br>PASSWORD_REQUIRE_COMPLEX | parameter value              |

The `UNLIMITED` and `DEFAULT` parameter values are stored in `pg_profile` as `-1` and `-2`, respectively.

## 54.40. `pg_publication`

The catalog `pg_publication` contains all publications created in the database. For more on publications see [Section 30.1](#).

**Table 54.40. `pg_publication` Columns**

| Column Type  | Description    |
|--------------|----------------|
| oid oid      | Row identifier |
| pubname name |                |

| Column Type                                              | Description                                                                                                                                                                |
|----------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                                          | Name of the publication                                                                                                                                                    |
| pubowner oid (references <a href="#">pg_authid</a> .oid) | Owner of the publication                                                                                                                                                   |
| puballtables bool                                        | If true, this publication automatically includes all tables in the database, including any that will be created in the future.                                             |
| pubinsert bool                                           | If true, <a href="#">INSERT</a> operations are replicated for tables in the publication.                                                                                   |
| pubupdate bool                                           | If true, <a href="#">UPDATE</a> operations are replicated for tables in the publication.                                                                                   |
| pubdelete bool                                           | If true, <a href="#">DELETE</a> operations are replicated for tables in the publication.                                                                                   |
| pubtruncate bool                                         | If true, <a href="#">TRUNCATE</a> operations are replicated for tables in the publication.                                                                                 |
| pubviaroot bool                                          | If true, operations on a leaf partition are replicated using the identity and schema of its top-most partitioned ancestor mentioned in the publication instead of its own. |

## 54.41. [pg\\_publication\\_rel](#)

The catalog [pg\\_publication\\_rel](#) contains the mapping between relations and publications in the database. This is a many-to-many mapping. See also [Section 54.82](#) for a more user-friendly view of this information.

**Table 54.41. [pg\\_publication\\_rel](#) Columns**

| Column Type                                                  | Description              |
|--------------------------------------------------------------|--------------------------|
| oid oid                                                      | Row identifier           |
| prpubid oid (references <a href="#">pg_publication</a> .oid) | Reference to publication |
| prrelid oid (references <a href="#">pg_class</a> .oid)       | Reference to relation    |

## 54.42. [pg\\_range](#)

The catalog [pg\\_range](#) stores information about range types. This is in addition to the types' entries in [pg\\_type](#).

**Table 54.42. [pg\\_range](#) Columns**

| Column Type                                                     | Description                                          |
|-----------------------------------------------------------------|------------------------------------------------------|
| rngtypeid oid (references <a href="#">pg_type</a> .oid)         | OID of the range type                                |
| rngsubtype oid (references <a href="#">pg_type</a> .oid)        | OID of the element type (subtype) of this range type |
| rngmultitypid oid (references <a href="#">pg_type</a> .oid)     | OID of the multirange type for this range type       |
| rngcollation oid (references <a href="#">pg_collation</a> .oid) |                                                      |

| Column Type                                                               | Description                                                                                                  |
|---------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------|
|                                                                           | OID of the collation used for range comparisons, or zero if none                                             |
| <code>rngsubopc oid</code> (references <code>pg_opclass .oid</code> )     | OID of the subtype's operator class used for range comparisons                                               |
| <code>rngcanonical regproc</code> (references <code>pg_proc .oid</code> ) | OID of the function to convert a range value into canonical form, or zero if none                            |
| <code>rngsubdiff regproc</code> (references <code>pg_proc .oid</code> )   | OID of the function to return the difference between two element values as double precision, or zero if none |

`rngsubopc` (plus `rngcollation`, if the element type is collatable) determines the sort ordering used by the range type. `rngcanonical` is used when the element type is discrete. `rngsubdiff` is optional but should be supplied to improve performance of GiST indexes on the range type.

## 54.43. `pg_replication_origin`

The `pg_replication_origin` catalog contains all replication origins created. For more on replication origins see [Chapter 52](#).

Unlike most system catalogs, `pg_replication_origin` is shared across all databases of a cluster: there is only one copy of `pg_replication_origin` per cluster, not one per database.

**Table 54.43. `pg_replication_origin` Columns**

| Column Type              | Description                                                                                  |
|--------------------------|----------------------------------------------------------------------------------------------|
| <code>roident oid</code> | A unique, cluster-wide identifier for the replication origin. Should never leave the system. |
| <code>roname text</code> | The external, user defined, name of a replication origin.                                    |

## 54.44. `pg_rewrite`

The catalog `pg_rewrite` stores rewrite rules for tables and views.

**Table 54.44. `pg_rewrite` Columns**

| Column Type                                                        | Description                                                                                                                                                                                                   |
|--------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>oid oid</code>                                               | Row identifier                                                                                                                                                                                                |
| <code>rulename name</code>                                         | Rule name                                                                                                                                                                                                     |
| <code>ev_class oid</code> (references <code>pg_class .oid</code> ) | The table this rule is for                                                                                                                                                                                    |
| <code>ev_type char</code>                                          | Event type that the rule is for: 1 = <a href="#">SELECT</a> , 2 = <a href="#">UPDATE</a> , 3 = <a href="#">INSERT</a> , 4 = <a href="#">DELETE</a>                                                            |
| <code>ev_enabled char</code>                                       | Controls in which <a href="#">session replication role</a> modes the rule fires. O = rule fires in “origin” and “local” modes, D = rule is disabled, R = rule fires in “replica” mode, A = rule fires always. |
| <code>is_instead bool</code>                                       | True if the rule is an <code>INSTEAD</code> rule                                                                                                                                                              |
| <code>ev_qual pg_node_tree</code>                                  |                                                                                                                                                                                                               |

| Column Type                         | Description                                                                                                       |
|-------------------------------------|-------------------------------------------------------------------------------------------------------------------|
|                                     | Expression tree (in the form of a <code>nodeToString()</code> representation) for the rule's qualifying condition |
| <code>ev_action pg_node_tree</code> | Query tree (in the form of a <code>nodeToString()</code> representation) for the rule's action                    |

### Note

`pg_class.relhasrules` must be true if a table has any rules in this catalog.

## 54.45. pg\_role\_password

The catalog `pg_role_password` records role's passwords history used to enforce authentication restrictions.

Unlike most system catalogs, `pg_role_password` is shared across all databases of a cluster: there is only one copy of `pg_role_password` per cluster, not one per database.

**Table 54.45. pg\_role\_password Columns**

| Column Type                                                             | Description                               |
|-------------------------------------------------------------------------|-------------------------------------------|
| <code>passrole regrole</code> (references <code>pg_authid .oid</code> ) | The OID of the role                       |
| <code>passpassword text</code>                                          | Password of the role (possibly encrypted) |
| <code>passsetat timestamptz</code>                                      | Password set time                         |

## 54.46. pg\_seclabel

The catalog `pg_seclabel` stores security labels on database objects. Security labels can be manipulated with the `SECURITY LABEL` command. For an easier way to view security labels, see [Section 54.87](#).

See also `pg_shseclabel`, which performs a similar function for security labels of database objects that are shared across a database cluster.

**Table 54.46. pg\_seclabel Columns**

| Column Type                                                        | Description                                                                                                                                                                                       |
|--------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>objoid oid</code> (references any OID column)                | The OID of the object this security label pertains to                                                                                                                                             |
| <code>classoid oid</code> (references <code>pg_class .oid</code> ) | The OID of the system catalog this object appears in                                                                                                                                              |
| <code>objsubid int4</code>                                         | For a security label on a table column, this is the column number (the <code>objoid</code> and <code>classoid</code> refer to the table itself). For all other object types, this column is zero. |
| <code>provider text</code>                                         | The label provider associated with this label.                                                                                                                                                    |
| <code>label text</code>                                            | The security label applied to this object.                                                                                                                                                        |

## 54.47. pg\_sequence

The catalog `pg_sequence` contains information about sequences. Some of the information about sequences, such as the name and the schema, is in [pg\\_class](#)

**Table 54.47. pg\_sequence Columns**

| Column Type                                                          | Description                                                     |
|----------------------------------------------------------------------|-----------------------------------------------------------------|
| <code>seqrelid oid</code> (references <a href="#">pg_class</a> .oid) | The OID of the <a href="#">pg_class</a> entry for this sequence |
| <code>seqtypid oid</code> (references <a href="#">pg_type</a> .oid)  | Data type of the sequence                                       |
| <code>seqstart int8</code>                                           | Start value of the sequence                                     |
| <code>seqincrement int8</code>                                       | Increment value of the sequence                                 |
| <code>seqmax int8</code>                                             | Maximum value of the sequence                                   |
| <code>seqmin int8</code>                                             | Minimum value of the sequence                                   |
| <code>seqcache int8</code>                                           | Cache size of the sequence                                      |
| <code>seqcycle bool</code>                                           | Whether the sequence cycles                                     |

## 54.48. pg\_shdepend

The catalog `pg_shdepend` records the dependency relationships between database objects and shared objects, such as roles. This information allows Postgres Pro to ensure that those objects are unreferenced before attempting to delete them.

See also [pg\\_depend](#), which performs a similar function for dependencies involving objects within a single database.

Unlike most system catalogs, `pg_shdepend` is shared across all databases of a cluster: there is only one copy of `pg_shdepend` per cluster, not one per database.

**Table 54.48. pg\_shdepend Columns**

| Column Type                                                         | Description                                                                                                                                                                 |
|---------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>dbid oid</code> (references <a href="#">pg_database</a> .oid) | The OID of the database the dependent object is in, or zero for a shared object or a <code>SHARED_DEPENDENCY_PIN</code> entry                                               |
| <code>classid oid</code> (references <a href="#">pg_class</a> .oid) | The OID of the system catalog the dependent object is in, or zero for a <code>SHARED_DEPENDENCY_PIN</code> entry                                                            |
| <code>objid oid</code> (references any OID column)                  | The OID of the specific dependent object, or zero for a <code>SHARED_DEPENDENCY_PIN</code> entry                                                                            |
| <code>objsubid int4</code>                                          | For a table column, this is the column number (the <code>objid</code> and <code>classid</code> refer to the table itself). For all other object types, this column is zero. |

| Column Type                                            | Description                                                                          |
|--------------------------------------------------------|--------------------------------------------------------------------------------------|
| refclassid oid (references <code>pg_class</code> .oid) | The OID of the system catalog the referenced object is in (must be a shared catalog) |
| refobjid oid (references any OID column)               | The OID of the specific referenced object                                            |
| deptype char                                           | A code defining the specific semantics of this dependency relationship; see text     |

In all cases, a `pg_shdepend` entry indicates that the referenced object cannot be dropped without also dropping the dependent object. However, there are several subflavors identified by `deptype`:

`SHARED_DEPENDENCY_OWNER` (o)

The referenced object (which must be a role) is the owner of the dependent object.

`SHARED_DEPENDENCY_ACL` (a)

The referenced object (which must be a role) is mentioned in the ACL (access control list, i.e., privileges list) of the dependent object. (A `SHARED_DEPENDENCY_ACL` entry is not made for the owner of the object, since the owner will have a `SHARED_DEPENDENCY_OWNER` entry anyway.)

`SHARED_DEPENDENCY_POLICY` (r)

The referenced object (which must be a role) is mentioned as the target of a dependent policy object.

`SHARED_DEPENDENCY_PIN` (p)

There is no dependent object; this type of entry is a signal that the system itself depends on the referenced object, and so that object must never be deleted. Entries of this type are created only by `initdb`. The columns for the dependent object contain zeroes.

`SHARED_DEPENDENCY_TABLESPACE` (t)

The referenced object (which must be a tablespace) is mentioned as the tablespace for a relation that doesn't have storage.

Other dependency flavors might be needed in future. Note in particular that the current definition only supports roles and tablespaces as referenced objects.

## 54.49. `pg_shdescription`

The catalog `pg_shdescription` stores optional descriptions (comments) for shared database objects. Descriptions can be manipulated with the `COMMENT` command and viewed with `psql`'s `\d` commands.

See also `pg_description`, which performs a similar function for descriptions involving objects within a single database.

Unlike most system catalogs, `pg_shdescription` is shared across all databases of a cluster: there is only one copy of `pg_shdescription` per cluster, not one per database.

**Table 54.49. `pg_shdescription` Columns**

| Column Type                                          | Description                                          |
|------------------------------------------------------|------------------------------------------------------|
| objoid oid (references any OID column)               | The OID of the object this description pertains to   |
| classoid oid (references <code>pg_class</code> .oid) | The OID of the system catalog this object appears in |
| description text                                     |                                                      |

| Column Type | Description                                                  |
|-------------|--------------------------------------------------------------|
|             | Arbitrary text that serves as the description of this object |

## 54.50. pg\_shseclabel

The catalog `pg_shseclabel` stores security labels on shared database objects. Security labels can be manipulated with the `SECURITY LABEL` command. For an easier way to view security labels, see [Section 54.87](#).

See also `pg_seclabel`, which performs a similar function for security labels involving objects within a single database.

Unlike most system catalogs, `pg_shseclabel` is shared across all databases of a cluster: there is only one copy of `pg_shseclabel` per cluster, not one per database.

**Table 54.50. pg\_shseclabel Columns**

| Column Type                                                       | Description                                           |
|-------------------------------------------------------------------|-------------------------------------------------------|
| <code>objoid oid</code> (references any OID column)               | The OID of the object this security label pertains to |
| <code>classoid oid</code> (references <code>pg_class.oid</code> ) | The OID of the system catalog this object appears in  |
| <code>provider text</code>                                        | The label provider associated with this label.        |
| <code>label text</code>                                           | The security label applied to this object.            |

## 54.51. pg\_statistic

The catalog `pg_statistic` stores statistical data about the contents of the database. Entries are created by `ANALYZE` and subsequently used by the query planner. Note that all the statistical data is inherently approximate, even assuming that it is up-to-date.

Normally there is one entry, with `stainherit = false`, for each table column that has been analyzed. If the table has inheritance children, a second entry with `stainherit = true` is also created. This row represents the column's statistics over the inheritance tree, i.e., statistics for the data you'd see with `SELECT column FROM table*`, whereas the `stainherit = false` row represents the results of `SELECT column FROM ONLY table`.

`pg_statistic` also stores statistical data about the values of index expressions. These are described as if they were actual data columns; in particular, `starelid` references the index. No entry is made for an ordinary non-expression index column, however, since it would be redundant with the entry for the underlying table column. Currently, entries for index expressions always have `stainherit = false`.

Since different kinds of statistics might be appropriate for different kinds of data, `pg_statistic` is designed not to assume very much about what sort of statistics it stores. Only extremely general statistics (such as nullness) are given dedicated columns in `pg_statistic`. Everything else is stored in “slots”, which are groups of associated columns whose content is identified by a code number in one of the slot's columns.

`pg_statistic` should not be readable by the public, since even statistical information about a table's contents might be considered sensitive. (Example: minimum and maximum values of a salary column might be quite interesting.) `pg_stats` is a publicly readable view on `pg_statistic` that only exposes information about those tables that are readable by the current user.

**Table 54.51. `pg_statistic` Columns**

| Column Type                                                                | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
|----------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>starelid oid</code> (references <code>pg_class</code> .oid)          | The table or index that the described column belongs to                                                                                                                                                                                                                                                                                                                                                                                                                  |
| <code>staattnum int2</code> (references <code>pg_attribute</code> .attnum) | The number of the described column                                                                                                                                                                                                                                                                                                                                                                                                                                       |

| <code>stanullfrac float4</code>                                            | The fraction of the column's entries that are null                                                                                                                                                                                                                                                                                                                                                                                                                       |
| <code>stawidth int4</code>                                                 | The average stored width, in bytes, of nonnull entries                                                                                                                                                                                                                                                                                                                                                                                                                   |
| <code>stadistinct float4</code>                                            | The number of distinct nonnull data values in the column. A value greater than zero is the actual number of distinct values. A value less than zero is the negative of a multiplier for the number of rows in the table; for example, a column in which about 80% of the values are nonnull and each nonnull value appears about twice on average could be represented by <code>stadistinct = -0.4</code> . A zero value means the number of distinct values is unknown. |
| <code>stakindN int2</code>                                                 | A code number indicating the kind of statistics stored in the <i>N</i> th “slot” of the <code>pg_statistic</code> row.                                                                                                                                                                                                                                                                                                                                                   |
| <code>staopN oid</code> (references <code>pg_operator</code> .oid)         | An operator used to derive the statistics stored in the <i>N</i> th “slot”. For example, a histogram slot would show the < operator that defines the sort order of the data. Zero if the statistics kind does not require an operator.                                                                                                                                                                                                                                   |
| <code>stacollN oid</code> (references <code>pg_collation</code> .oid)      | The collation used to derive the statistics stored in the <i>N</i> th “slot”. For example, a histogram slot for a collatable column would show the collation that defines the sort order of the data. Zero for noncollatable data.                                                                                                                                                                                                                                       |
| <code>stanumbersN float4[]</code>                                          | Numerical statistics of the appropriate kind for the <i>N</i> th “slot”, or null if the slot kind does not involve numerical values                                                                                                                                                                                                                                                                                                                                      |
| <code>stavaluesN anyarray</code>                                           | Column data values of the appropriate kind for the <i>N</i> th “slot”, or null if the slot kind does not store any data values. Each array's element values are actually of the specific column's data type, or a related type such as an array's element type, so there is no way to define these columns' type more specifically than <code>anyarray</code> .                                                                                                          |

## 54.52. `pg_statistic_ext`

The catalog `pg_statistic_ext` holds definitions of extended planner statistics. Each row in this catalog corresponds to a *statistics object* created with `CREATE STATISTICS`.

**Table 54.52. `pg_statistic_ext` Columns**

| Column Type                                                       | Description    |
|-------------------------------------------------------------------|----------------|
| <code>oid oid</code>                                              | Row identifier |
| <code>stxrelid oid</code> (references <code>pg_class</code> .oid) |                |

| Column Type                                                          | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                           |

| stxowner oid (references <a href="#">pg_authid</a> .oid)             | Owner of the statistics object                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| stxstattarget int4                                                   | <code>stxstattarget</code> controls the level of detail of statistics accumulated for this statistics object by <a href="#">ANALYZE</a> . A zero value indicates that no statistics should be collected. A negative value says to use the maximum of the statistics targets of the referenced columns, if set, or the system default statistics target. Positive values of <code>stxstattarget</code> determine the target number of “most common values” to collect. |
| stxkeys int2vector (references <a href="#">pg_attribute</a> .attnum) | An array of attribute numbers, indicating which table columns are covered by this statistics object; for example a value of <code>1 3</code> would mean that the first and the third table columns are covered                                                                                                                                                                                                                                                        |
| stxkind char[]                                                       | An array containing codes for the enabled statistics kinds; valid values are: <code>d</code> for n-distinct statistics, <code>f</code> for functional dependency statistics, <code>m</code> for most common values (MCV) list statistics, and <code>e</code> for expression statistics                                                                                                                                                                                |
| stxexprs pg_node_tree                                                | Expression trees (in <code>nodeToString()</code> representation) for statistics object attributes that are not simple column references. This is a list with one element per expression. Null if all statistics object attributes are simple references.                                                                                                                                                                                                              |

The `pg_statistic_ext` entry is filled in completely during [CREATE STATISTICS](#), but the actual statistical values are not computed then. Subsequent [ANALYZE](#) commands compute the desired values and populate an entry in the `pg_statistic_ext_data` catalog.

## 54.53. pg\_statistic\_ext\_data

The catalog `pg_statistic_ext_data` holds data for extended planner statistics defined in `pg_statistic_ext`. Each row in this catalog corresponds to a *statistics object* created with [CREATE STATISTICS](#).

Like `pg_statistic`, `pg_statistic_ext_data` should not be readable by the public, since the contents might be considered sensitive. (Example: most common combinations of values in columns might be quite interesting.) `pg_stats_ext` is a publicly readable view on `pg_statistic_ext_data` (after joining with `pg_statistic_ext`) that only exposes information about tables the current user owns.

**Table 54.53. pg\_statistic\_ext\_data Columns**

| Column Type                                                   | Description                                                                       |
|---------------------------------------------------------------|-----------------------------------------------------------------------------------|
| stxoid oid (references <a href="#">pg_statistic_ext</a> .oid) | Extended statistics object containing the definition for this data                |
| stxdndistinct pg_ndistinct                                    | N-distinct counts, serialized as <code>pg_ndistinct</code> type                   |
| stxddependencies pg_dependencies                              | Functional dependency statistics, serialized as <code>pg_dependencies</code> type |
| stxdmcv pg_mcv_list                                           |                                                                                   |

| Column Type                          | Description                                                                           |
|--------------------------------------|---------------------------------------------------------------------------------------|
|                                      | MCV (most-common values) list statistics, serialized as <code>pg_mcv_list</code> type |
| <code>stxdexpr pg_statistic[]</code> | Per-expression statistics, serialized as an array of <code>pg_statistic</code> type   |

## 54.54. pg\_subscription

The catalog `pg_subscription` contains all existing logical replication subscriptions. For more information about logical replication see [Chapter 30](#).

Unlike most system catalogs, `pg_subscription` is shared across all databases of a cluster: there is only one copy of `pg_subscription` per cluster, not one per database.

Access to the column `subconninfo` is revoked from normal users, because it could contain plain-text passwords.

**Table 54.54. pg\_subscription Columns**

| Column Type                                            | Description                                                                                                                                                       |
|--------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>oid oid</code>                                   | Row identifier                                                                                                                                                    |
| <code>subdbid oid (references pg_database .oid)</code> | OID of the database that the subscription resides in                                                                                                              |
| <code>subname name</code>                              | Name of the subscription                                                                                                                                          |
| <code>subowner oid (references pg_authid .oid)</code>  | Owner of the subscription                                                                                                                                         |
| <code>subenabled bool</code>                           | If true, the subscription is enabled and should be replicating                                                                                                    |
| <code>subbinary bool</code>                            | If true, the subscription will request that the publisher send data in binary format                                                                              |
| <code>substream bool</code>                            | If true, the subscription will allow streaming of in-progress transactions                                                                                        |
| <code>subconninfo text</code>                          | Connection string to the upstream database                                                                                                                        |
| <code>subslotname name</code>                          | Name of the replication slot in the upstream database (also used for the local replication origin name); null represents <code>NONE</code>                        |
| <code>subsynccommit text</code>                        | The <code>synchronous_commit</code> setting for the subscription's workers to use                                                                                 |
| <code>subpublications text[]</code>                    | Array of subscribed publication names. These reference publications defined in the upstream database. For more on publications see <a href="#">Section 30.1</a> . |

## 54.55. pg\_subscription\_rel

The catalog `pg_subscription_rel` contains the state for each replicated relation in each subscription. This is a many-to-many mapping.

This catalog only contains tables known to the subscription after running either `CREATE SUBSCRIPTION` or `ALTER SUBSCRIPTION ... REFRESH PUBLICATION`.

**Table 54.55. pg\_subscription\_rel Columns**

| Column Type                                                   | Description                                                                                                                     |
|---------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------|
| srsubid oid (references <a href="#">pg_subscription</a> .oid) | Reference to subscription                                                                                                       |
| srrelid oid (references <a href="#">pg_class</a> .oid)        | Reference to relation                                                                                                           |
| srsubstate char                                               | State code: i = initialize, d = data is being copied, f = finished table copy, s = synchronized, r = ready (normal replication) |
| srsublsn pg_lsn                                               | Remote LSN of the state change used for synchronization coordination when in s or r states, otherwise null                      |

## 54.56. pg\_tablespace

The catalog `pg_tablespace` stores information about the available tablespaces. Tables can be placed in particular tablespaces to aid administration of disk layout.

Unlike most system catalogs, `pg_tablespace` is shared across all databases of a cluster: there is only one copy of `pg_tablespace` per cluster, not one per database.

**Table 54.56. pg\_tablespace Columns**

| Column Type                                              | Description                                                    |
|----------------------------------------------------------|----------------------------------------------------------------|
| oid oid                                                  | Row identifier                                                 |
| spcname name                                             | Tablespace name                                                |
| spcowner oid (references <a href="#">pg_authid</a> .oid) | Owner of the tablespace, usually the user who created it       |
| spcacl aclitem[]                                         | Access privileges; see <a href="#">Section 5.7</a> for details |
| spcoptions text[]                                        | Tablespace-level options, as “keyword=value” strings           |

## 54.57. pg\_transform

The catalog `pg_transform` stores information about transforms, which are a mechanism to adapt data types to procedural languages. See [CREATE TRANSFORM](#) for more information.

**Table 54.57. pg\_transform Columns**

| Column Type                                                  | Description                                |
|--------------------------------------------------------------|--------------------------------------------|
| oid oid                                                      | Row identifier                             |
| trftype oid (references <a href="#">pg_type</a> .oid)        | OID of the data type this transform is for |
| trflang oid (references <a href="#">pg_language</a> .oid)    | OID of the language this transform is for  |
| trffromsql regproc (references <a href="#">pg_proc</a> .oid) |                                            |

| Column Type                                                | Description                                                                                                                                                                           |
|------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                                            | The OID of the function to use when converting the data type for input to the procedural language (e.g., function parameters). Zero is stored if the default behavior should be used. |
| trftosql regproc (references <a href="#">pg_proc</a> .oid) | The OID of the function to use when converting output from the procedural language (e.g., return values) to the data type. Zero is stored if the default behavior should be used.     |

## 54.58. pg\_trigger

The catalog `pg_trigger` stores triggers on tables and views. See [CREATE TRIGGER](#) for more information.

**Table 54.58. pg\_trigger Columns**

| Column Type                                                      | Description                                                                                                                                                                                                                  |
|------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| oid oid                                                          | Row identifier                                                                                                                                                                                                               |
| tgrelid oid (references <a href="#">pg_class</a> .oid)           | The table this trigger is on                                                                                                                                                                                                 |
| tgparentid oid (references <a href="#">pg_trigger</a> .oid)      | Parent trigger that this trigger is cloned from (this happens when partitions are created or attached to a partitioned table); zero if not a clone                                                                           |
| tgname name                                                      | Trigger name (must be unique among triggers of same table)                                                                                                                                                                   |
| tgfoid oid (references <a href="#">pg_proc</a> .oid)             | The function to be called                                                                                                                                                                                                    |
| tgtype int2                                                      | Bit mask identifying trigger firing conditions                                                                                                                                                                               |
| tgenabled char                                                   | Controls in which <a href="#">session_replication_role</a> modes the trigger fires. O = trigger fires in “origin” and “local” modes, D = trigger is disabled, R = trigger fires in “replica” mode, A = trigger fires always. |
| tgisinternal bool                                                | True if trigger is internally generated (usually, to enforce the constraint identified by <code>tgconstraint</code> )                                                                                                        |
| tgconstrrelid oid (references <a href="#">pg_class</a> .oid)     | The table referenced by a referential integrity constraint (zero if trigger is not for a referential integrity constraint)                                                                                                   |
| tgconstrindid oid (references <a href="#">pg_class</a> .oid)     | The index supporting a unique, primary key, referential integrity, or exclusion constraint (zero if trigger is not for one of these types of constraint)                                                                     |
| tgconstraint oid (references <a href="#">pg_constraint</a> .oid) | The <a href="#">pg_constraint</a> entry associated with the trigger (zero if trigger is not for a constraint)                                                                                                                |
| tgdeferrable bool                                                | True if constraint trigger is deferrable                                                                                                                                                                                     |
| tginitdeferred bool                                              | True if constraint trigger is initially deferred                                                                                                                                                                             |
| tgargs int2                                                      | Number of argument strings passed to trigger function                                                                                                                                                                        |

| Column Type                                                                    | Description                                                                                                                    |
|--------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------|
| <code>tgattr int2vector</code> (references <code>pg_attribute .attnum</code> ) | Column numbers, if trigger is column-specific; otherwise an empty array                                                        |
| <code>tgargs bytea</code>                                                      | Argument strings to pass to trigger, each NULL-terminated                                                                      |
| <code>tgqual pg_node_tree</code>                                               | Expression tree (in <code>nodeToString()</code> representation) for the trigger's <code>WHEN</code> condition, or null if none |
| <code>tgoldtable name</code>                                                   | REFERENCING clause name for <code>OLD TABLE</code> , or null if none                                                           |
| <code>tgnewtable name</code>                                                   | REFERENCING clause name for <code>NEW TABLE</code> , or null if none                                                           |

Currently, column-specific triggering is supported only for `UPDATE` events, and so `tgattr` is relevant only for that event type. `tgtype` might contain bits for other event types as well, but those are presumed to be table-wide regardless of what is in `tgattr`.

### Note

When `tgconstraint` is nonzero, `tgconstrrelid`, `tgconstrindid`, `tgdeferrable`, and `tginitdeferred` are largely redundant with the referenced `pg_constraint` entry. However, it is possible for a non-deferrable trigger to be associated with a deferrable constraint: foreign key constraints can have some deferrable and some non-deferrable triggers.

### Note

`pg_class.relhastriggers` must be true if a relation has any triggers in this catalog.

## 54.59. pg\_ts\_config

The `pg_ts_config` catalog contains entries representing text search configurations. A configuration specifies a particular text search parser and a list of dictionaries to use for each of the parser's output token types. The parser is shown in the `pg_ts_config` entry, but the token-to-dictionary mapping is defined by subsidiary entries in `pg_ts_config_map`.

Postgres Pro's text search features are described at length in [Chapter 12](#).

**Table 54.59. `pg_ts_config` Columns**

| Column Type                                                                | Description                                               |
|----------------------------------------------------------------------------|-----------------------------------------------------------|
| <code>oid oid</code>                                                       | Row identifier                                            |
| <code>cfgname name</code>                                                  | Text search configuration name                            |
| <code>cfgnamespace oid</code> (references <code>pg_namespace .oid</code> ) | The OID of the namespace that contains this configuration |
| <code>cfgowner oid</code> (references <code>pg_authid .oid</code> )        | Owner of the configuration                                |
| <code>cfgparser oid</code> (references <code>pg_ts_parser .oid</code> )    |                                                           |

| Column Type                                              |
|----------------------------------------------------------|
| Description                                              |
| The OID of the text search parser for this configuration |

## 54.60. pg\_ts\_config\_map

The `pg_ts_config_map` catalog contains entries showing which text search dictionaries should be consulted, and in what order, for each output token type of each text search configuration's parser.

Postgres Pro's text search features are described at length in [Chapter 12](#).

**Table 54.60. pg\_ts\_config\_map Columns**

| Column Type                                                                                                                    |
|--------------------------------------------------------------------------------------------------------------------------------|
| Description                                                                                                                    |
| mapcfg oid (references <code>pg_ts_config</code> .oid)<br>The OID of the <code>pg_ts_config</code> entry owning this map entry |
| maptokentype int4<br>A token type emitted by the configuration's parser                                                        |
| mapseqno int4<br>Order in which to consult this entry (lower <code>mapseqnos</code> first)                                     |
| mapdict oid (references <code>pg_ts_dict</code> .oid)<br>The OID of the text search dictionary to consult                      |

## 54.61. pg\_ts\_dict

The `pg_ts_dict` catalog contains entries defining text search dictionaries. A dictionary depends on a text search template, which specifies all the implementation functions needed; the dictionary itself provides values for the user-settable parameters supported by the template. This division of labor allows dictionaries to be created by unprivileged users. The parameters are specified by a text string `dictinitoption`, whose format and meaning vary depending on the template.

Postgres Pro's text search features are described at length in [Chapter 12](#).

**Table 54.61. pg\_ts\_dict Columns**

| Column Type                                                                                                               |
|---------------------------------------------------------------------------------------------------------------------------|
| Description                                                                                                               |
| oid oid<br>Row identifier                                                                                                 |
| dictname name<br>Text search dictionary name                                                                              |
| dictnamespace oid (references <code>pg_namespace</code> .oid)<br>The OID of the namespace that contains this dictionary   |
| dictowner oid (references <code>pg_authid</code> .oid)<br>Owner of the dictionary                                         |
| dicttemplate oid (references <code>pg_ts_template</code> .oid)<br>The OID of the text search template for this dictionary |
| dictinitoption text<br>Initialization option string for the template                                                      |

## 54.62. pg\_ts\_parser

The `pg_ts_parser` catalog contains entries defining text search parsers. A parser is responsible for splitting input text into lexemes and assigning a token type to each lexeme. Since a parser must be implemented by C-language-level functions, creation of new parsers is restricted to database superusers.

Postgres Pro's text search features are described at length in [Chapter 12](#).

**Table 54.62. `pg_ts_parser` Columns**

| Column Type                                                     | Description                                          |
|-----------------------------------------------------------------|------------------------------------------------------|
| oid oid                                                         | Row identifier                                       |
| prsname name                                                    | Text search parser name                              |
| prsnamespace oid (references <a href="#">pg_namespace</a> .oid) | The OID of the namespace that contains this parser   |
| prsstart regproc (references <a href="#">pg_proc</a> .oid)      | OID of the parser's startup function                 |
| prstoken regproc (references <a href="#">pg_proc</a> .oid)      | OID of the parser's next-token function              |
| prsend regproc (references <a href="#">pg_proc</a> .oid)        | OID of the parser's shutdown function                |
| prsheadline regproc (references <a href="#">pg_proc</a> .oid)   | OID of the parser's headline function (zero if none) |
| prsllextype regproc (references <a href="#">pg_proc</a> .oid)   | OID of the parser's lextype function                 |

## 54.63. `pg_ts_template`

The `pg_ts_template` catalog contains entries defining text search templates. A template is the implementation skeleton for a class of text search dictionaries. Since a template must be implemented by C-language-level functions, creation of new templates is restricted to database superusers.

Postgres Pro's text search features are described at length in [Chapter 12](#).

**Table 54.63. `pg_ts_template` Columns**

| Column Type                                                      | Description                                                  |
|------------------------------------------------------------------|--------------------------------------------------------------|
| oid oid                                                          | Row identifier                                               |
| tmplname name                                                    | Text search template name                                    |
| tmplnamespace oid (references <a href="#">pg_namespace</a> .oid) | The OID of the namespace that contains this template         |
| tmplinit regproc (references <a href="#">pg_proc</a> .oid)       | OID of the template's initialization function (zero if none) |
| tmpllexize regproc (references <a href="#">pg_proc</a> .oid)     | OID of the template's lexize function                        |

## 54.64. `pg_type`

The catalog `pg_type` stores information about data types. Base types and enum types (scalar types) are created with [CREATE TYPE](#), and domains with [CREATE DOMAIN](#). A composite type is automatically created for each table in the database, to represent the row structure of the table. It is also possible to create composite types with `CREATE TYPE AS`.

**Table 54.64. pg\_type Columns**

| Column Type                                                     | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|-----------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| oid oid                                                         | Row identifier                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| typname name                                                    | Data type name                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| typnamespace oid (references <a href="#">pg_namespace</a> .oid) | The OID of the namespace that contains this type                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| typowner oid (references <a href="#">pg_authid</a> .oid)        | Owner of the type                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| typlen int2                                                     | For a fixed-size type, <code>typlen</code> is the number of bytes in the internal representation of the type. But for a variable-length type, <code>typlen</code> is negative. -1 indicates a “varlena” type (one that has a length word), -2 indicates a null-terminated C string.                                                                                                                                                                                                                                                                                             |
| typbyval bool                                                   | <code>typbyval</code> determines whether internal routines pass a value of this type by value or by reference. <code>typbyval</code> had better be false if <code>typlen</code> is not 1, 2, or 4 (or 8 on machines where Datum is 8 bytes). Variable-length types are always passed by reference. Note that <code>typbyval</code> can be false even if the length would allow pass-by-value.                                                                                                                                                                                   |
| typtype char                                                    | <code>typtype</code> is <code>b</code> for a base type, <code>c</code> for a composite type (e.g., a table's row type), <code>d</code> for a domain, <code>e</code> for an enum type, <code>p</code> for a pseudo-type, <code>r</code> for a range type, or <code>m</code> for a multirange type. See also <code>typrelid</code> and <code>typbasetype</code> .                                                                                                                                                                                                                 |
| typcategory char                                                | <code>typcategory</code> is an arbitrary classification of data types that is used by the parser to determine which implicit casts should be “preferred”. See <a href="#">Table 54.65</a> .                                                                                                                                                                                                                                                                                                                                                                                     |
| typispreferred bool                                             | True if the type is a preferred cast target within its <code>typcategory</code>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| typisdefined bool                                               | True if the type is defined, false if this is a placeholder entry for a not-yet-defined type. When <code>typisdefined</code> is false, nothing except the type name, namespace, and OID can be relied on.                                                                                                                                                                                                                                                                                                                                                                       |
| typdelim char                                                   | Character that separates two values of this type when parsing array input. Note that the delimiter is associated with the array element data type, not the array data type.                                                                                                                                                                                                                                                                                                                                                                                                     |
| typrelid oid (references <a href="#">pg_class</a> .oid)         | If this is a composite type (see <code>typtype</code> ), then this column points to the <code>pg_class</code> entry that defines the corresponding table. (For a free-standing composite type, the <code>pg_class</code> entry doesn't really represent a table, but it is needed anyway for the type's <code>pg_attribute</code> entries to link to.) Zero for non-composite types.                                                                                                                                                                                            |
| typsubscript regproc (references <a href="#">pg_proc</a> .oid)  | Subscripting handler function's OID, or zero if this type doesn't support subscripting. Types that are “true” array types have <code>typsubscript</code> = <code>array_subscript_handler</code> , but other types may have other handler functions to implement specialized subscripting behavior.                                                                                                                                                                                                                                                                              |
| typelem oid (references <a href="#">pg_type</a> .oid)           | If <code>typelem</code> is not zero then it identifies another row in <code>pg_type</code> , defining the type yielded by subscripting. This should be zero if <code>typsubscript</code> is zero. However, it can be zero when <code>typsubscript</code> isn't zero, if the handler doesn't need <code>typelem</code> to determine the subscripting result type. Note that a <code>typelem</code> dependency is considered to imply physical containment of the element type in this type; so DDL changes on the element type might be restricted by the presence of this type. |

| Column Type                                                             | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |

| <code>typanalyze regproc</code> (references <code>pg_proc .oid</code> ) | Custom <code>ANALYZE</code> function, or zero to use the standard function                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| <code>typalign char</code>                                              | <p><code>typalign</code> is the alignment required when storing a value of this type. It applies to storage on disk as well as most representations of the value inside Postgres Pro. When multiple values are stored consecutively, such as in the representation of a complete row on disk, padding is inserted before a datum of this type so that it begins on the specified boundary. The alignment reference is the beginning of the first datum in the sequence. Possible values are:</p> <ul style="list-style-type: none"> <li>• <code>c</code> = char alignment, i.e., no alignment needed.</li> <li>• <code>s</code> = short alignment (2 bytes on most machines).</li> <li>• <code>i</code> = int alignment (4 bytes on most machines).</li> <li>• <code>d</code> = double alignment (8 bytes on many machines, but by no means all).</li> </ul>                                                                                                            |
| <code>typstorage char</code>                                            | <p><code>typstorage</code> tells for varlena types (those with <code>typflen = -1</code>) if the type is prepared for toasting and what the default strategy for attributes of this type should be. Possible values are:</p> <ul style="list-style-type: none"> <li>• <code>p</code> (plain): Values must always be stored plain (non-varlena types always use this value).</li> <li>• <code>e</code> (external): Values can be stored in a secondary “TOAST” relation (if relation has one, see <code>pg_class.reltoastrelid</code> ).</li> <li>• <code>m</code> (main): Values can be compressed and stored inline.</li> <li>• <code>x</code> (extended): Values can be compressed and/or moved to a secondary relation.</li> </ul> <p><code>x</code> is the usual choice for toast-able types. Note that <code>m</code> values can also be moved out to secondary storage, but only as a last resort (<code>e</code> and <code>x</code> values are moved first).</p> |
| <code>typnotnull bool</code>                                            | <code>typnotnull</code> represents a not-null constraint on a type. Used for domains only.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| <code>typbasetype oid</code> (references <code>pg_type .oid</code> )    | If this is a domain (see <code>typtype</code> ), then <code>typbasetype</code> identifies the type that this one is based on. Zero if this type is not a domain.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| <code>typtypmod int4</code>                                             | Domains use <code>typtypmod</code> to record the <code>typmod</code> to be applied to their base type (-1 if base type does not use a <code>typmod</code> ). -1 if this type is not a domain.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |

| Column Type                                                                | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|----------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>typndims int4</code>                                                 | <code>typndims</code> is the number of array dimensions for a domain over an array (that is, <code>typbasetype</code> is an array type). Zero for types other than domains over array types.                                                                                                                                                                                                                                                                                                         |
| <code>typcollation oid</code> (references <code>pg_collation .oid</code> ) | <code>typcollation</code> specifies the collation of the type. If the type does not support collations, this will be zero. A base type that supports collations will have a nonzero value here, typically <code>DEFAULT_COLLATION_OID</code> . A domain over a collatable type can have a collation OID different from its base type's, if one was specified for the domain.                                                                                                                         |
| <code>typdefaultbin pg_node_tree</code>                                    | If <code>typdefaultbin</code> is not null, it is the <code>nodeToString()</code> representation of a default expression for the type. This is only used for domains.                                                                                                                                                                                                                                                                                                                                 |
| <code>typdefault text</code>                                               | <code>typdefault</code> is null if the type has no associated default value. If <code>typdefaultbin</code> is not null, <code>typdefault</code> must contain a human-readable version of the default expression represented by <code>typdefaultbin</code> . If <code>typdefaultbin</code> is null and <code>typdefault</code> is not, then <code>typdefault</code> is the external representation of the type's default value, which can be fed to the type's input converter to produce a constant. |
| <code>typacl aclitem[]</code>                                              | Access privileges; see <a href="#">Section 5.7</a> for details                                                                                                                                                                                                                                                                                                                                                                                                                                       |

### Note

For fixed-width types used in system tables, it is critical that the size and alignment defined in `pg_type` agree with the way that the compiler will lay out the column in a structure representing a table row.

[Table 54.65](#) lists the system-defined values of `typcategory`. Any future additions to this list will also be upper-case ASCII letters. All other ASCII characters are reserved for user-defined categories.

**Table 54.65. `typcategory` Codes**

| Code | Category              |
|------|-----------------------|
| A    | Array types           |
| B    | Boolean types         |
| C    | Composite types       |
| D    | Date/time types       |
| E    | Enum types            |
| G    | Geometric types       |
| I    | Network address types |
| N    | Numeric types         |
| P    | Pseudo-types          |
| R    | Range types           |
| S    | String types          |
| T    | Timespan types        |
| U    | User-defined types    |
| V    | Bit-string types      |
| X    | unknown type          |

## 54.65. pg\_user\_mapping

The catalog `pg_user_mapping` stores the mappings from local user to remote. Access to this catalog is restricted from normal users, use the view `pg_user_mappings` instead.

**Table 54.66. pg\_user\_mapping Columns**

| Column Type                                                   | Description                                                               |
|---------------------------------------------------------------|---------------------------------------------------------------------------|
| <code>oid oid</code>                                          | Row identifier                                                            |
| <code>umuser oid (references pg_authid .oid)</code>           | OID of the local role being mapped, or zero if the user mapping is public |
| <code>umserver oid (references pg_foreign_server .oid)</code> | The OID of the foreign server that contains this mapping                  |
| <code>umoptions text[]</code>                                 | User mapping specific options, as “keyword=value” strings                 |

## 54.66. System Views

In addition to the system catalogs, Postgres Pro provides a number of built-in views. Some system views provide convenient access to some commonly used queries on the system catalogs. Other views provide access to internal server state.

The information schema ([Chapter 39](#)) provides an alternative set of views which overlap the functionality of the system views. Since the information schema is SQL-standard whereas the views described here are Postgres Pro-specific, it's usually better to use the information schema if it provides all the information you need.

[Table 54.67](#) lists the system views described here. More detailed documentation of each view follows below. There are some additional views that provide access to the results of the statistics collector; they are described in [Table 27.2](#).

Except where noted, all the views described here are read-only.

**Table 54.67. System Views**

| View Name                                    | Purpose                                                      |
|----------------------------------------------|--------------------------------------------------------------|
| <code>pg_available_extensions</code>         | available extensions                                         |
| <code>pg_available_extension_versions</code> | available versions of extensions                             |
| <code>pg_backend_memory_contexts</code>      | backend memory contexts                                      |
| <code>pg_config</code>                       | compile-time configuration parameters                        |
| <code>pg_cursors</code>                      | open cursors                                                 |
| <code>pg_file_settings</code>                | summary of configuration file contents                       |
| <code>pg_group</code>                        | groups of database users                                     |
| <code>pg_hba_file_rules</code>               | summary of client authentication configuration file contents |
| <code>pg_indexes</code>                      | indexes                                                      |
| <code>pg_locks</code>                        | locks currently held or awaited                              |
| <code>pg_matviews</code>                     | materialized views                                           |
| <code>pg_policies</code>                     | policies                                                     |
| <code>pg_prepared_statements</code>          | prepared statements                                          |

| View Name                                    | Purpose                                                               |
|----------------------------------------------|-----------------------------------------------------------------------|
| <a href="#">pg_autoprepared_statements</a>   | autoprepared statements                                               |
| <a href="#">pg_prepared_xacts</a>            | prepared transactions                                                 |
| <a href="#">pg_publication_tables</a>        | publications and their associated tables                              |

## 54.67. [pg\\_available\\_extensions](#)

The [pg\\_available\\_extensions](#) view lists the extensions that are available for installation. See also the [pg\\_extension](#) catalog, which shows the extensions currently installed.

**Table 54.68. [pg\\_available\\_extensions](#) Columns**

| Column Type                            | Description                                                            |
|----------------------------------------|------------------------------------------------------------------------|
| <a href="#">name</a> name              | Extension name                                                         |
| <a href="#">default_version</a> text   | Name of default version, or NULL if none is specified                  |
| <a href="#">installed_version</a> text | Currently installed version of the extension, or NULL if not installed |
| <a href="#">comment</a> text           | Comment string from the extension's control file                       |

The [pg\\_available\\_extensions](#) view is read-only.

## 54.68. [pg\\_available\\_extension\\_versions](#)

The [pg\\_available\\_extension\\_versions](#) view lists the specific extension versions that are available for installation. See also the [pg\\_extension](#) catalog, which shows the extensions currently installed.

**Table 54.69. pg\_available\_extension\_versions Columns**

| Column Type      | Description                                                                                                          |
|------------------|----------------------------------------------------------------------------------------------------------------------|
| name name        | Extension name                                                                                                       |
| version text     | Version name                                                                                                         |
| installed bool   | True if this version of this extension is currently installed                                                        |
| superuser bool   | True if only superusers are allowed to install this extension (but see <code>trusted</code> )                        |
| trusted bool     | True if the extension can be installed by non-superusers with appropriate privileges                                 |
| relocatable bool | True if extension can be relocated to another schema                                                                 |
| schema name      | Name of the schema that the extension must be installed into, or <code>NULL</code> if partially or fully relocatable |
| requires name[]  | Names of prerequisite extensions, or <code>NULL</code> if none                                                       |
| comment text     | Comment string from the extension's control file                                                                     |

The `pg_available_extension_versions` view is read-only.

## 54.69. pg\_backend\_memory\_contexts

The view `pg_backend_memory_contexts` displays all the memory contexts of the server process attached to the current session.

`pg_backend_memory_contexts` contains one row for each memory context.

**Table 54.70. pg\_backend\_memory\_contexts Columns**

| Column Type        | Description                                                                             |
|--------------------|-----------------------------------------------------------------------------------------|
| name text          | Name of the memory context                                                              |
| ident text         | Identification information of the memory context. This field is truncated at 1024 bytes |
| parent text        | Name of the parent of this memory context                                               |
| level int4         | Distance from <code>TopMemoryContext</code> in context tree                             |
| total_bytes int8   | Total bytes allocated for this memory context                                           |
| total_nblocks int8 | Total number of blocks allocated for this memory context                                |
| free_bytes int8    | Free space in bytes                                                                     |

| Column Type                   | Description                 |
|-------------------------------|-----------------------------|
| <code>free_chunks int8</code> | Total number of free chunks |
| <code>used_bytes int8</code>  | Used space in bytes         |

By default, the `pg_backend_memory_contexts` view can be read only by superusers.

## 54.70. `pg_config`

The view `pg_config` describes the compile-time configuration parameters of the currently installed version of Postgres Pro. It is intended, for example, to be used by software packages that want to interface to Postgres Pro to facilitate finding the required header files and libraries. It provides the same basic information as the [pg\\_config](#) Postgres Pro client application.

By default, the `pg_config` view can be read only by superusers.

**Table 54.71. `pg_config` Columns**

| Column Type               | Description         |
|---------------------------|---------------------|
| <code>name text</code>    | The parameter name  |
| <code>setting text</code> | The parameter value |

## 54.71. `pg_cursors`

The `pg_cursors` view lists the cursors that are currently available. Cursors can be defined in several ways:

- via the [DECLARE](#) statement in SQL
- via the Bind message in the frontend/backend protocol, as described in [Section 55.2.3](#)
- via the Server Programming Interface (SPI), as described in [Section 49.1](#)

The `pg_cursors` view displays cursors created by any of these means. Cursors only exist for the duration of the transaction that defines them, unless they have been declared `WITH HOLD`. Therefore non-holdable cursors are only present in the view until the end of their creating transaction.

### Note

Cursors are used internally to implement some of the components of Postgres Pro, such as procedural languages. Therefore, the `pg_cursors` view might include cursors that have not been explicitly created by the user.

**Table 54.72. `pg_cursors` Columns**

| Column Type                 | Description            |
|-----------------------------|------------------------|
| <code>name text</code>      | The name of the cursor |
| <code>statement text</code> |                        |

| Column Type                            | Description                                                                                                                                                          |
|----------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                        | The verbatim query string submitted to declare this cursor                                                                                                           |
| <code>is_holdable bool</code>          | <code>true</code> if the cursor is holdable (that is, it can be accessed after the transaction that declared the cursor has committed); <code>false</code> otherwise |
| <code>is_binary bool</code>            | <code>true</code> if the cursor was declared <code>BINARY</code> ; <code>false</code> otherwise                                                                      |
| <code>is_scrollable bool</code>        | <code>true</code> if the cursor is scrollable (that is, it allows rows to be retrieved in a nonsequential manner); <code>false</code> otherwise                      |
| <code>creation_time timestamptz</code> | The time at which the cursor was declared                                                                                                                            |

The `pg_cursors` view is read-only.

## 54.72. `pg_file_settings`

The view `pg_file_settings` provides a summary of the contents of the server's configuration file(s). A row appears in this view for each “name = value” entry appearing in the files, with annotations indicating whether the value could be applied successfully. Additional row(s) may appear for problems not linked to a “name = value” entry, such as syntax errors in the files.

This view is helpful for checking whether planned changes in the configuration files will work, or for diagnosing a previous failure. Note that this view reports on the *current* contents of the files, not on what was last applied by the server. (The `pg_settings` view is usually sufficient to determine that.)

By default, the `pg_file_settings` view can be read only by superusers.

**Table 54.73. `pg_file_settings` Columns**

| Column Type                  | Description                                                                  |
|------------------------------|------------------------------------------------------------------------------|
| <code>sourcefile text</code> | Full path name of the configuration file                                     |
| <code>sourceline int4</code> | Line number within the configuration file where the entry appears            |
| <code>seqno int4</code>      | Order in which the entries are processed (1.. <i>n</i> )                     |
| <code>name text</code>       | Configuration parameter name                                                 |
| <code>setting text</code>    | Value to be assigned to the parameter                                        |
| <code>applied bool</code>    | <code>True</code> if the value can be applied successfully                   |
| <code>error text</code>      | If not null, an error message indicating why this entry could not be applied |

If the configuration file contains syntax errors or invalid parameter names, the server will not attempt to apply any settings from it, and therefore all the `applied` fields will read as false. In such a case there will be one or more rows with non-null `error` fields indicating the problem(s). Otherwise, individual settings will be applied if possible. If an individual setting cannot be applied (e.g., invalid value, or the setting cannot be changed after server start) it will have an appropriate message in the `error` field. Another way

that an entry might have `applied = false` is that it is overridden by a later entry for the same parameter name; this case is not considered an error so nothing appears in the `error` field.

See [Section 19.1](#) for more information about the various ways to change run-time parameters.

## 54.73. `pg_group`

The view `pg_group` exists for backwards compatibility: it emulates a catalog that existed in PostgreSQL before version 8.1. It shows the names and members of all roles that are marked as `not rolcanlogin`, which is an approximation to the set of roles that are being used as groups.

**Table 54.74. `pg_group` Columns**

| Column Type                                                             | Description                                            |
|-------------------------------------------------------------------------|--------------------------------------------------------|
| <code>groname name</code> (references <code>pg_authid .rolname</code> ) | Name of the group                                      |
| <code>grosysid oid</code> (references <code>pg_authid .oid</code> )     | ID of this group                                       |
| <code>grolist oid[]</code> (references <code>pg_authid .oid</code> )    | An array containing the IDs of the roles in this group |

## 54.74. `pg_hba_file_rules`

The view `pg_hba_file_rules` provides a summary of the contents of the client authentication configuration file, `pg_hba.conf`. A row appears in this view for each non-empty, non-comment line in the file, with annotations indicating whether the rule could be applied successfully.

This view can be helpful for checking whether planned changes in the authentication configuration file will work, or for diagnosing a previous failure. Note that this view reports on the *current* contents of the file, not on what was last loaded by the server.

By default, the `pg_hba_file_rules` view can be read only by superusers.

**Table 54.75. `pg_hba_file_rules` Columns**

| Column Type                   | Description                                                                                                                           |
|-------------------------------|---------------------------------------------------------------------------------------------------------------------------------------|
| <code>line_number int4</code> | Line number of this rule in <code>pg_hba.conf</code>                                                                                  |
| <code>type text</code>        | Type of connection                                                                                                                    |
| <code>database text[]</code>  | List of database name(s) to which this rule applies                                                                                   |
| <code>user_name text[]</code> | List of user and group name(s) to which this rule applies                                                                             |
| <code>address text</code>     | Host name or IP address, or one of <code>all</code> , <code>samehost</code> , or <code>samenet</code> , or null for local connections |
| <code>netmask text</code>     | IP address mask, or null if not applicable                                                                                            |
| <code>auth_method text</code> | Authentication method                                                                                                                 |
| <code>options text[]</code>   | Options specified for authentication method, if any                                                                                   |

| Column Type | Description                                                                   |
|-------------|-------------------------------------------------------------------------------|
| error text  | If not null, an error message indicating why this line could not be processed |

Usually, a row reflecting an incorrect entry will have values for only the `line_number` and `error` fields.

See [Chapter 20](#) for more information about client authentication configuration.

## 54.75. pg\_indexes

The view `pg_indexes` provides access to useful information about each index in the database.

**Table 54.76. pg\_indexes Columns**

| Column Type                                                         | Description                                                             |
|---------------------------------------------------------------------|-------------------------------------------------------------------------|
| schemaname name (references <a href="#">pg_namespace</a> .nspname)  | Name of schema containing table and index                               |
| tablename name (references <a href="#">pg_class</a> .relname)       | Name of table the index is for                                          |
| indexname name (references <a href="#">pg_class</a> .relname)       | Name of index                                                           |
| tablespace name (references <a href="#">pg_tablespace</a> .spcname) | Name of tablespace containing index (null if default for database)      |
| indexdef text                                                       | Index definition (a reconstructed <a href="#">CREATE INDEX</a> command) |

## 54.76. pg\_locks

The view `pg_locks` provides access to information about the locks held by active processes within the database server. See [Chapter 13](#) for more discussion of locking.

`pg_locks` contains one row per active lockable object, requested lock mode, and relevant process. Thus, the same lockable object might appear many times, if multiple processes are holding or waiting for locks on it. However, an object that currently has no locks on it will not appear at all.

There are several distinct types of lockable objects: whole relations (e.g., tables), individual pages of relations, individual tuples of relations, transaction IDs (both virtual and permanent IDs), and general database objects (identified by class OID and object OID, in the same way as in [pg\\_description](#) or [pg\\_depend](#)). Also, the right to extend a relation is represented as a separate lockable object, as is the right to update `pg_database.datfrozenxid`. Also, “advisory” locks can be taken on numbers that have user-defined meanings.

**Table 54.77. pg\_locks Columns**

| Column Type                                                | Description                                                                                                                                                                         |
|------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| locktype text                                              | Type of the lockable object: relation, extend, frozenid, page, tuple, transactionid, virtualxid, spectoken, object, userlock, or advisory. (See also <a href="#">Table 27.11</a> .) |
| database oid (references <a href="#">pg_database</a> .oid) | OID of the database in which the lock target exists, or zero if the target is a shared object, or null if the target is a transaction ID                                            |

| Column Type                                                        | Description                                                                                                                                                                                                                         |
|--------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>relation oid</code> (references <code>pg_class .oid</code> ) | OID of the relation targeted by the lock, or null if the target is not a relation or part of a relation                                                                                                                             |
| <code>page int4</code>                                             | Page number targeted by the lock within the relation, or null if the target is not a relation page or tuple                                                                                                                         |
| <code>tuple int2</code>                                            | Tuple number targeted by the lock within the page, or null if the target is not a tuple                                                                                                                                             |
| <code>virtualxid text</code>                                       | Virtual ID of the transaction targeted by the lock, or null if the target is not a virtual transaction ID                                                                                                                           |
| <code>transactionid xid</code>                                     | ID of the transaction targeted by the lock, or null if the target is not a transaction ID                                                                                                                                           |
| <code>classid oid</code> (references <code>pg_class .oid</code> )  | OID of the system catalog containing the lock target, or null if the target is not a general database object                                                                                                                        |
| <code>objid oid</code> (references any OID column)                 | OID of the lock target within its system catalog, or null if the target is not a general database object                                                                                                                            |
| <code>objsubid int2</code>                                         | Column number targeted by the lock (the <code>classid</code> and <code>objid</code> refer to the table itself), or zero if the target is some other general database object, or null if the target is not a general database object |
| <code>virtualtransaction text</code>                               | Virtual ID of the transaction that is holding or awaiting this lock                                                                                                                                                                 |
| <code>pid int4</code>                                              | Process ID of the server process holding or awaiting this lock, or null if the lock is held by a prepared transaction                                                                                                               |
| <code>mode text</code>                                             | Name of the lock mode held or desired by this process (see <a href="#">Section 13.3.1</a> and <a href="#">Section 13.2.3</a> )                                                                                                      |
| <code>granted bool</code>                                          | True if lock is held, false if lock is awaited                                                                                                                                                                                      |
| <code>fastpath bool</code>                                         | True if lock was taken via fast path, false if taken via main lock table                                                                                                                                                            |
| <code>waitstart timestampz</code>                                  | Time when the server process started waiting for this lock, or null if the lock is held. Note that this can be null for a very short period of time after the wait started even though <code>granted</code> is false.               |

`granted` is true in a row representing a lock held by the indicated process. False indicates that this process is currently waiting to acquire this lock, which implies that at least one other process is holding or waiting for a conflicting lock mode on the same lockable object. The waiting process will sleep until the other lock is released (or a deadlock situation is detected). A single process can be waiting to acquire at most one lock at a time.

Throughout running a transaction, a server process holds an exclusive lock on the transaction's virtual transaction ID. If a permanent ID is assigned to the transaction (which normally happens only if the transaction changes the state of the database), it also holds an exclusive lock on the transaction's permanent transaction ID until it ends. When a process finds it necessary to wait specifically for another transaction to end, it does so by attempting to acquire share lock on the other transaction's ID (either

virtual or permanent ID depending on the situation). That will succeed only when the other transaction terminates and releases its locks.

Although tuples are a lockable type of object, information about row-level locks is stored on disk, not in memory, and therefore row-level locks normally do not appear in this view. If a process is waiting for a row-level lock, it will usually appear in the view as waiting for the permanent transaction ID of the current holder of that row lock.

Advisory locks can be acquired on keys consisting of either a single `bigint` value or two integer values. A `bigint` key is displayed with its high-order half in the `classid` column, its low-order half in the `objid` column, and `objsubid` equal to 1. The original `bigint` value can be reassembled with the expression `(classid::bigint << 32) | objid::bigint`. Integer keys are displayed with the first key in the `classid` column, the second key in the `objid` column, and `objsubid` equal to 2. The actual meaning of the keys is up to the user. Advisory locks are local to each database, so the `database` column is meaningful for an advisory lock.

`pg_locks` provides a global view of all locks in the database cluster, not only those relevant to the current database. Although its `relation` column can be joined against `pg_class.oid` to identify locked relations, this will only work correctly for relations in the current database (those for which the `database` column is either the current database's OID or zero).

The `pid` column can be joined to the `pid` column of the `pg_stat_activity` view to get more information on the session holding or awaiting each lock, for example

```
SELECT * FROM pg_locks pl LEFT JOIN pg_stat_activity psa
    ON pl.pid = psa.pid;
```

Also, if you are using prepared transactions, the `virtualtransaction` column can be joined to the `transaction` column of the `pg_prepared_xacts` view to get more information on prepared transactions that hold locks. (A prepared transaction can never be waiting for a lock, but it continues to hold the locks it acquired while running.) For example:

```
SELECT * FROM pg_locks pl LEFT JOIN pg_prepared_xacts ppx
    ON pl.virtualtransaction = '-1/' || ppx.transaction;
```

While it is possible to obtain information about which processes block which other processes by joining `pg_locks` against itself, this is very difficult to get right in detail. Such a query would have to encode knowledge about which lock modes conflict with which others. Worse, the `pg_locks` view does not expose information about which processes are ahead of which others in lock wait queues, nor information about which processes are parallel workers running on behalf of which other client sessions. It is better to use the `pg_blocking_pids()` function (see [Table 9.65](#)) to identify which process(es) a waiting process is blocked behind.

The `pg_locks` view displays data from both the regular lock manager and the predicate lock manager, which are separate systems; in addition, the regular lock manager subdivides its locks into regular and *fast-path* locks. This data is not guaranteed to be entirely consistent. When the view is queried, data on fast-path locks (with `fastpath = true`) is gathered from each backend one at a time, without freezing the state of the entire lock manager, so it is possible for locks to be taken or released while information is gathered. Note, however, that these locks are known not to conflict with any other lock currently in place. After all backends have been queried for fast-path locks, the remainder of the regular lock manager is locked as a unit, and a consistent snapshot of all remaining locks is collected as an atomic action. After unlocking the regular lock manager, the predicate lock manager is similarly locked and all predicate locks are collected as an atomic action. Thus, with the exception of fast-path locks, each lock manager will deliver a consistent set of results, but as we do not lock both lock managers simultaneously, it is possible for locks to be taken or released after we interrogate the regular lock manager and before we interrogate the predicate lock manager.

Locking the regular and/or predicate lock manager could have some impact on database performance if this view is very frequently accessed. The locks are held only for the minimum amount of time necessary to obtain data from the lock managers, but this does not completely eliminate the possibility of a performance impact.

## 54.77. pg\_matviews

The view `pg_matviews` provides access to useful information about each materialized view in the database.

**Table 54.78. pg\_matviews Columns**

| Column                    | Type                                                                             | Description                                                                    |
|---------------------------|----------------------------------------------------------------------------------|--------------------------------------------------------------------------------|
| <code>schemaname</code>   | <code>name</code> (references <code>pg_namespace</code> <code>.nspname</code> )  | Name of schema containing materialized view                                    |
| <code>matviewname</code>  | <code>name</code> (references <code>pg_class</code> <code>.relname</code> )      | Name of materialized view                                                      |
| <code>matviewowner</code> | <code>name</code> (references <code>pg_authid</code> <code>.rolname</code> )     | Name of materialized view's owner                                              |
| <code>tablespace</code>   | <code>name</code> (references <code>pg_tablespace</code> <code>.spcname</code> ) | Name of tablespace containing materialized view (null if default for database) |
| <code>hasindexes</code>   | <code>bool</code>                                                                | True if materialized view has (or recently had) any indexes                    |
| <code>ispopulated</code>  | <code>bool</code>                                                                | True if materialized view is currently populated                               |
| <code>definition</code>   | <code>text</code>                                                                | Materialized view definition (a reconstructed <code>SELECT</code> query)       |

## 54.78. pg\_policies

The view `pg_policies` provides access to useful information about each row-level security policy in the database.

**Table 54.79. pg\_policies Columns**

| Column                  | Type                                                                            | Description                                                                                              |
|-------------------------|---------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------|
| <code>schemaname</code> | <code>name</code> (references <code>pg_namespace</code> <code>.nspname</code> ) | Name of schema containing table policy is on                                                             |
| <code>tablename</code>  | <code>name</code> (references <code>pg_class</code> <code>.relname</code> )     | Name of table policy is on                                                                               |
| <code>policyname</code> | <code>name</code> (references <code>pg_policy</code> <code>.polname</code> )    | Name of policy                                                                                           |
| <code>permissive</code> | <code>text</code>                                                               | Is the policy permissive or restrictive?                                                                 |
| <code>roles</code>      | <code>name[]</code>                                                             | The roles to which this policy applies                                                                   |
| <code>cmd</code>        | <code>text</code>                                                               | The command type to which the policy is applied                                                          |
| <code>qual</code>       | <code>text</code>                                                               | The expression added to the security barrier qualifications for queries that this policy applies to      |
| <code>with_check</code> | <code>text</code>                                                               | The expression added to the WITH CHECK qualifications for queries that attempt to add rows to this table |

## 54.79. pg\_prepared\_statements

The `pg_prepared_statements` view displays all the prepared statements that are available in the current session. See [PREPARE](#) for more information about prepared statements.

`pg_prepared_statements` contains one row for each prepared statement. Rows are added to the view when a new prepared statement is created and removed when a prepared statement is released (for example, via the [DEALLOCATE](#) command).

**Table 54.80. `pg_prepared_statements` Columns**

| Column Type                            | Description                                                                                                                                                                                                                                                                                                    |
|----------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>name text</code>                 | The identifier of the prepared statement                                                                                                                                                                                                                                                                       |
| <code>statement text</code>            | The query string submitted by the client to create this prepared statement. For prepared statements created via SQL, this is the <code>PREPARE</code> statement submitted by the client. For prepared statements created via the frontend/backend protocol, this is the text of the prepared statement itself. |
| <code>prepare_time timestamptz</code>  | The time at which the prepared statement was created                                                                                                                                                                                                                                                           |
| <code>parameter_types regtype[]</code> | The expected parameter types for the prepared statement in the form of an array of <code>regtype</code> . The OID corresponding to an element of this array can be obtained by casting the <code>regtype</code> value to <code>oid</code> .                                                                    |
| <code>from_sql bool</code>             | <code>true</code> if the prepared statement was created via the <code>PREPARE</code> SQL command; <code>false</code> if the statement was prepared via the frontend/backend protocol                                                                                                                           |
| <code>generic_plans int8</code>        | Number of times generic plan was chosen                                                                                                                                                                                                                                                                        |
| <code>custom_plans int8</code>         | Number of times custom plan was chosen                                                                                                                                                                                                                                                                         |

The `pg_prepared_statements` view is read-only.

## 54.80. `pg_autoprepared_statements`

The `pg_autoprepared_statements` view displays all the autoprepared statements that are available in the current session. See [Section 14.6](#) for more information about autoprepared statements.

**Table 54.81. `pg_autoprepared_statements` Columns**

| Name                         | Type                   | Description                                                                                                                                                                                                                                     |
|------------------------------|------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>statement</code>       | <code>text</code>      | The query string submitted by the client from which this prepared statement was created. Note that literals in this string are not replaced with prepared statement placeholders.                                                               |
| <code>parameter_types</code> | <code>regtype[]</code> | The expected parameter types for the autoprepared statement in the form of an array of <code>regtype</code> . The OID corresponding to an element of this array can be obtained by casting the <code>regtype</code> value to <code>oid</code> . |

| Name                    | Type              | Description                                  |
|-------------------------|-------------------|----------------------------------------------|
| <code>exec_count</code> | <code>int8</code> | Number of times this statement was executed. |

The `pg_autoprepared_statements` view is read only.

## 54.81. `pg_prepared_xacts`

The view `pg_prepared_xacts` displays information about transactions that are currently prepared for two-phase commit (see [PREPARE TRANSACTION](#) for details).

`pg_prepared_xacts` contains one row per prepared transaction. An entry is removed when the transaction is committed or rolled back.

**Table 54.82. `pg_prepared_xacts` Columns**

| Column Type                                                               | Description                                                                 |
|---------------------------------------------------------------------------|-----------------------------------------------------------------------------|
| <code>transaction xid</code>                                              | Numeric transaction identifier of the prepared transaction                  |
| <code>gid text</code>                                                     | Global transaction identifier that was assigned to the transaction          |
| <code>prepared timestampz</code>                                          | Time at which the transaction was prepared for commit                       |
| <code>owner name (references <code>pg_authid</code> .rolname)</code>      | Name of the user that executed the transaction                              |
| <code>database name (references <code>pg_database</code> .datname)</code> | Name of the database in which the transaction was executed                  |
| <code>state3pc text</code>                                                | State of the three-phase commit (used only by <a href="#">multimaster</a> ) |

When the `pg_prepared_xacts` view is accessed, the internal transaction manager data structures are momentarily locked, and a copy is made for the view to display. This ensures that the view produces a consistent set of results, while not blocking normal operations longer than necessary. Nonetheless there could be some impact on database performance if this view is frequently accessed.

## 54.82. `pg_publication_tables`

The view `pg_publication_tables` provides information about the mapping between publications and the tables they contain. Unlike the underlying catalog `pg_publication_rel`, this view expands publications defined as `FOR ALL TABLES`, so for such publications there will be a row for each eligible table.

**Table 54.83. `pg_publication_tables` Columns**

| Column Type                                                                  | Description                     |
|------------------------------------------------------------------------------|---------------------------------|
| <code>pubname name (references <code>pg_publication</code> .pubname)</code>  | Name of publication             |
| <code>schemaname name (references <code>pg_namespace</code> .nspname)</code> | Name of schema containing table |
| <code>tablename name (references <code>pg_class</code> .relname)</code>      | Name of table                   |

## 54.83. `pg_replication_origin_status`

The `pg_replication_origin_status` view contains information about how far replay for a certain origin has progressed. For more on replication origins see [Chapter 52](#).

**Table 54.84. `pg_replication_origin_status` Columns**

| Column Type                                                                            | Description                                                                                                                                                        |
|----------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>local_id oid</code> (references <code>pg_replication_origin .roident</code> )    | internal node identifier                                                                                                                                           |
| <code>external_id text</code> (references <code>pg_replication_origin .roname</code> ) | external node identifier                                                                                                                                           |
| <code>remote_lsn pg_lsn</code>                                                         | The origin node's LSN up to which data has been replicated.                                                                                                        |
| <code>local_lsn pg_lsn</code>                                                          | This node's LSN at which <code>remote_lsn</code> has been replicated. Used to flush commit records before persisting data to disk when using asynchronous commits. |

## 54.84. `pg_replication_slots`

The `pg_replication_slots` view provides a listing of all replication slots that currently exist on the database cluster, along with their current state.

For more on replication slots, see [Section 26.2.6](#) and [Chapter 51](#).

**Table 54.85. `pg_replication_slots` Columns**

| Column Type                                                                | Description                                                                                                                                                  |
|----------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>slot_name name</code>                                                | A unique, cluster-wide identifier for the replication slot                                                                                                   |
| <code>plugin name</code>                                                   | The base name of the shared object containing the output plugin this logical slot is using, or null for physical slots.                                      |
| <code>slot_type text</code>                                                | The slot type: <code>physical</code> or <code>logical</code>                                                                                                 |
| <code>datoid oid</code> (references <code>pg_database .oid</code> )        | The OID of the database this slot is associated with, or null. Only logical slots have an associated database.                                               |
| <code>database name</code> (references <code>pg_database .datname</code> ) | The name of the database this slot is associated with, or null. Only logical slots have an associated database.                                              |
| <code>temporary bool</code>                                                | True if this is a temporary replication slot. Temporary slots are not saved to disk and are automatically dropped on error or when the session has finished. |
| <code>active bool</code>                                                   | True if this slot is currently actively being used                                                                                                           |
| <code>active_pid int4</code>                                               | The process ID of the session using this slot if the slot is currently actively being used. <code>NULL</code> if inactive.                                   |
| <code>xmin xid</code>                                                      | The oldest transaction that this slot needs the database to retain. <code>VACUUM</code> cannot remove tuples deleted by any later transaction.               |
| <code>catalog_xmin xid</code>                                              |                                                                                                                                                              |

| Column Type                             | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
|-----------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                         | The oldest transaction affecting the system catalogs that this slot needs the database to retain. <code>VACUUM</code> cannot remove catalog tuples deleted by any later transaction.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| <code>restart_lsn pg_lsn</code>         | The address (LSN) of oldest WAL which still might be required by the consumer of this slot and thus won't be automatically removed during checkpoints unless this LSN gets behind more than <code>max_slot_wal_keep_size</code> from the current LSN. <code>NULL</code> if the LSN of this slot has never been reserved.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| <code>confirmed_flush_lsn pg_lsn</code> | The address (LSN) up to which the logical slot's consumer has confirmed receiving data. Data older than this is not available anymore. <code>NULL</code> for physical slots.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| <code>wal_status text</code>            | Availability of WAL files claimed by this slot. Possible values are: <ul style="list-style-type: none"> <li><code>reserved</code> means that the claimed files are within <code>max_wal_size</code> .</li> <li><code>extended</code> means that <code>max_wal_size</code> is exceeded but the files are still retained, either by the replication slot or by <code>wal_keep_size</code> .</li> <li><code>unreserved</code> means that the slot no longer retains the required WAL files and some of them are to be removed at the next checkpoint. This state can return to <code>reserved</code> or <code>extended</code>.</li> <li><code>lost</code> means that some required WAL files have been removed and this slot is no longer usable.</li> </ul> The last two states are seen only when <code>max_slot_wal_keep_size</code> is non-negative. |
| <code>safe_wal_size int8</code>         | The number of bytes that can be written to WAL such that this slot is not in danger of getting in state "lost". It is <code>NULL</code> for lost slots, as well as if <code>max_slot_wal_keep_size</code> is <code>-1</code> .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| <code>two_phase bool</code>             | True if the slot is enabled for decoding prepared transactions. Always false for physical slots.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |

## 54.85. pg\_roles

The view `pg_roles` provides access to information about database roles. This is simply a publicly readable view of `pg_authid` that blanks out the password field.

**Table 54.86. pg\_roles Columns**

| Column Type                      | Description                                                                                      |
|----------------------------------|--------------------------------------------------------------------------------------------------|
| <code>rolname name</code>        | Role name                                                                                        |
| <code>rolsuper bool</code>       | Role has superuser privileges                                                                    |
| <code>rolinherit bool</code>     | Role automatically inherits privileges of roles it is a member of                                |
| <code>rolcreaterole bool</code>  | Role can create more roles                                                                       |
| <code>rolcreatedb bool</code>    | Role can create databases                                                                        |
| <code>rolcanlogin bool</code>    | Role can log in. That is, this role can be given as the initial session authorization identifier |
| <code>rolreplication bool</code> |                                                                                                  |

| Column Type                                                        | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|--------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                                                    | Role is a replication role. A replication role can initiate replication connections and create and drop replication slots.                                                                                                                                                                                                                                                                                                                                         |
| rolconnlimit int4                                                  | For roles that can log in, this sets maximum number of concurrent connections this role can make. -1 means no limit.                                                                                                                                                                                                                                                                                                                                               |
| rolprofile regprofile (references <a href="#">pg_profile</a> .oid) | The OID of the role's profile                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| rolloginattempts int4                                              | Number of consecutive failed login attempts of a user. It is always 0 if <code>FAILED_LOGIN_ATTEMPTS</code> value of the corresponding role profile is <code>UNLIMITED</code> . After a successful login, <code>rolloginattempts</code> is reset to 0.                                                                                                                                                                                                             |
| rolstatus int2                                                     | Status of the role: 0 for the active role, 1 the role is manually locked (see <code>ACCOUNT LOCK</code> in <a href="#">ALTER ROLE</a> ), 2 the role is locked because of inactivity (see parameter <code>USER_INACTIVE_TIME</code> in <a href="#">CREATE PROFILE</a> ), 4 the role is locked because the number of consecutive authentication failures has reached the limit (see parameter <code>FAILED_LOGIN_ATTEMPTS</code> in <a href="#">CREATE PROFILE</a> ) |
| rollastlogin timestamptz                                           | The timestamp the role logged in last time                                                                                                                                                                                                                                                                                                                                                                                                                         |
| rolfirstfailedauth timestamptz                                     | The timestamp of the role's first authentication failure                                                                                                                                                                                                                                                                                                                                                                                                           |
| rolpassword text                                                   | Not the password (always reads as <code>*****</code> )                                                                                                                                                                                                                                                                                                                                                                                                             |
| rolvaliduntil timestamptz                                          | Password expiry time (only used for password authentication); null if no expiration                                                                                                                                                                                                                                                                                                                                                                                |
| rolpasssetat timestamptz                                           | Password set time (only used for password authentication); null if password is not set.                                                                                                                                                                                                                                                                                                                                                                            |
| rolbypassrls bool                                                  | Role bypasses every row-level security policy, see <a href="#">Section 5.8</a> for more information.                                                                                                                                                                                                                                                                                                                                                               |

| oid oid (references <a href="#">pg_authid</a> .oid)                | ID of role                                                                                                                                                                                                                                                                                                                                                                                                                                                         |

## 54.86. pg\_rules

The view `pg_rules` provides access to useful information about query rewrite rules.

**Table 54.87. pg\_rules Columns**

| Column Type                                                        | Description                     |
|--------------------------------------------------------------------|---------------------------------|
| schemaname name (references <a href="#">pg_namespace</a> .nspname) | Name of schema containing table |
| tablename name (references <a href="#">pg_class</a> .relname)      | Name of table the rule is for   |
| rulename name (references <a href="#">pg_rewrite</a> .rulename)    | Name of rule                    |
| definition text                                                    |                                 |

| Column Type | Description                                        |
|-------------|----------------------------------------------------|
|             | Rule definition (a reconstructed creation command) |

The `pg_rules` view excludes the `ON SELECT` rules of views and materialized views; those can be seen in `pg_views` and `pg_matviews`.

## 54.87. `pg_seclabels`

The view `pg_seclabels` provides information about security labels. It as an easier-to-query version of the `pg_seclabel` catalog.

**Table 54.88. `pg_seclabels` Columns**

| Column Type                                                                 | Description                                                                                                                                                                                       |
|-----------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>objoid oid</code> (references any OID column)                         | The OID of the object this security label pertains to                                                                                                                                             |
| <code>classoid oid</code> (references <code>pg_class .oid</code> )          | The OID of the system catalog this object appears in                                                                                                                                              |
| <code>objsubid int4</code>                                                  | For a security label on a table column, this is the column number (the <code>objoid</code> and <code>classoid</code> refer to the table itself). For all other object types, this column is zero. |
| <code>objtype text</code>                                                   | The type of object to which this label applies, as text.                                                                                                                                          |
| <code>objnamespace oid</code> (references <code>pg_namespace .oid</code> )  | The OID of the namespace for this object, if applicable; otherwise NULL.                                                                                                                          |
| <code>objname text</code>                                                   | The name of the object to which this label applies, as text.                                                                                                                                      |
| <code>provider text</code> (references <code>pg_seclabel .provider</code> ) | The label provider associated with this label.                                                                                                                                                    |
| <code>label text</code> (references <code>pg_seclabel .label</code> )       | The security label applied to this object.                                                                                                                                                        |

## 54.88. `pg_sequences`

The view `pg_sequences` provides access to useful information about each sequence in the database.

**Table 54.89. `pg_sequences` Columns**

| Column Type                                                                   | Description                        |
|-------------------------------------------------------------------------------|------------------------------------|
| <code>schemaname name</code> (references <code>pg_namespace .nspname</code> ) | Name of schema containing sequence |
| <code>sequencename name</code> (references <code>pg_class .relname</code> )   | Name of sequence                   |
| <code>sequenceowner name</code> (references <code>pg_authid .rolname</code> ) | Name of sequence's owner           |
| <code>data_type regtype</code> (references <code>pg_type .oid</code> )        | Data type of the sequence          |
| <code>start_value int8</code>                                                 | Start value of the sequence        |

| Column Type       | Description                                                                                                                                                                                                                                                                                                               |
|-------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| min_value int8    | Minimum value of the sequence                                                                                                                                                                                                                                                                                             |
| max_value int8    | Maximum value of the sequence                                                                                                                                                                                                                                                                                             |
| increment_by int8 | Increment value of the sequence                                                                                                                                                                                                                                                                                           |
| cycle bool        | Whether the sequence cycles                                                                                                                                                                                                                                                                                               |
| cache_size int8   | Cache size of the sequence                                                                                                                                                                                                                                                                                                |
| last_value int8   | The last sequence value written to disk. If caching is used, this value can be greater than the last value handed out from the sequence. Null if the sequence has not been read from yet. Also, if the current user does not have <code>USAGE</code> or <code>SELECT</code> privilege on the sequence, the value is null. |

## 54.89. pg\_settings

The view `pg_settings` provides access to run-time parameters of the server. It is essentially an alternative interface to the `SHOW` and `SET` commands. It also provides access to some facts about each parameter that are not directly available from `SHOW`, such as minimum and maximum values.

**Table 54.90. pg\_settings Columns**

| Column Type     | Description                                                          |
|-----------------|----------------------------------------------------------------------|
| name text       | Run-time configuration parameter name                                |
| setting text    | Current value of the parameter                                       |
| unit text       | Implicit unit of the parameter                                       |
| category text   | Logical group of the parameter                                       |
| short_desc text | A brief description of the parameter                                 |
| extra_desc text | Additional, more detailed, description of the parameter              |
| context text    | Context required to set the parameter's value (see below)            |
| vartype text    | Parameter type (bool, enum, integer, real, or string)                |
| source text     | Source of the current parameter value                                |
| min_val text    | Minimum allowed value of the parameter (null for non-numeric values) |
| max_val text    | Maximum allowed value of the parameter (null for non-numeric values) |
| enumvals text[] |                                                                      |

| Column Type                       | Description                                                                                                                                                                                                                                                                                           |
|-----------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                   | Allowed values of an enum parameter (null for non-enum values)                                                                                                                                                                                                                                        |
| <code>boot_val</code> text        | Parameter value assumed at server startup if the parameter is not otherwise set                                                                                                                                                                                                                       |
| <code>reset_val</code> text       | Value that <code>RESET</code> would reset the parameter to in the current session                                                                                                                                                                                                                     |
| <code>sourcefile</code> text      | Configuration file the current value was set in (null for values set from sources other than configuration files, or when examined by a user who is neither a superuser or a member of <code>pg_read_all_settings</code> ); helpful when using <code>include</code> directives in configuration files |
| <code>sourceline</code> int4      | Line number within the configuration file the current value was set at (null for values set from sources other than configuration files, or when examined by a user who is neither a superuser or a member of <code>pg_read_all_settings</code> ).                                                    |
| <code>pending_restart</code> bool | <code>true</code> if the value has been changed in the configuration file but needs a restart; or <code>false</code> otherwise.                                                                                                                                                                       |

There are several possible values of `context`. In order of decreasing difficulty of changing the setting, they are:

`internal`

These settings cannot be changed directly; they reflect internally determined values. Some of them may be adjustable by rebuilding the server with different configuration options, or by changing options supplied to `initdb`.

`postmaster`

These settings can only be applied when the server starts, so any change requires restarting the server. Values for these settings are typically stored in the `postgresql.conf` file, or passed on the command line when starting the server. Of course, settings with any of the lower `context` types can also be set at server start time.

`sighup`

Changes to these settings can be made in `postgresql.conf` without restarting the server. Send a `SIGHUP` signal to the postmaster to cause it to re-read `postgresql.conf` and apply the changes. The postmaster will also forward the `SIGHUP` signal to its child processes so that they all pick up the new value.

`superuser-backend`

Changes to these settings can be made in `postgresql.conf` without restarting the server. They can also be set for a particular session in the connection request packet (for example, via libpq's `PGOPTIONS` environment variable), but only if the connecting user is a superuser. However, these settings never change in a session after it is started. If you change them in `postgresql.conf`, send a `SIGHUP` signal to the postmaster to cause it to re-read `postgresql.conf`. The new values will only affect subsequently-launched sessions.

`backend`

Changes to these settings can be made in `postgresql.conf` without restarting the server. They can also be set for a particular session in the connection request packet (for example, via libpq's `PGOPTIONS` environment variable); any user can make such a change for their session. However, these settings never change in a session after it is started. If you change them in `postgresql.conf`, send

a SIGHUP signal to the postmaster to cause it to re-read `postgresql.conf`. The new values will only affect subsequently-launched sessions.

#### superuser

These settings can be set from `postgresql.conf`, or within a session via the `SET` command; but only superusers can change them via `SET`. Changes in `postgresql.conf` will affect existing sessions only if no session-local value has been established with `SET`.

#### user

These settings can be set from `postgresql.conf`, or within a session via the `SET` command. Any user is allowed to change their session-local value. Changes in `postgresql.conf` will affect existing sessions only if no session-local value has been established with `SET`.

See [Section 19.1](#) for more information about the various ways to change these parameters.

This view does not display [customized options](#) until the extension module that defines them has been loaded.

This view cannot be inserted into or deleted from, but it can be updated. An `UPDATE` applied to a row of `pg_settings` is equivalent to executing the `SET` command on that named parameter. The change only affects the value used by the current session. If an `UPDATE` is issued within a transaction that is later aborted, the effects of the `UPDATE` command disappear when the transaction is rolled back. Once the surrounding transaction is committed, the effects will persist until the end of the session, unless overridden by another `UPDATE` or `SET`.

## 54.90. pg\_shadow

The view `pg_shadow` exists for backwards compatibility: it emulates a catalog that existed in PostgreSQL before version 8.1. It shows properties of all roles that are marked as `rolcanlogin` in `pg_authid`.

The name stems from the fact that this table should not be readable by the public since it contains passwords. `pg_user` is a publicly readable view on `pg_shadow` that blanks out the password field.

**Table 54.91. pg\_shadow Columns**

| Column Type                                                | Description                                                                                                     |
|------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------|
| username name (references <code>pg_authid.rolname</code> ) | User name                                                                                                       |
| usesysid oid (references <code>pg_authid.oid</code> )      | ID of this user                                                                                                 |
| usecreatedb bool                                           | User can create databases                                                                                       |
| usesuper bool                                              | User is a superuser                                                                                             |
| userepl bool                                               | User can initiate streaming replication and put the system in and out of backup mode.                           |
| usebypassrls bool                                          | User bypasses every row-level security policy, see <a href="#">Section 5.8</a> for more information.            |
| passwd text                                                | Encrypted password; null if none. See <code>pg_authid</code> for details of how encrypted passwords are stored. |
| valuntil timestamptz                                       | Password expiry time (only used for password authentication)                                                    |
| useconfig text[]                                           |                                                                                                                 |

| Column Type | Description                                           |
|-------------|-------------------------------------------------------|
|             | Session defaults for run-time configuration variables |

## 54.91. pg\_shmem\_allocations

The `pg_shmem_allocations` view shows allocations made from the server's main shared memory segment. This includes both memory allocated by postgres itself and memory allocated by extensions using the mechanisms detailed in [Section 40.10.10](#).

Note that this view does not include memory allocated using the dynamic shared memory infrastructure.

**Table 54.92. pg\_shmem\_allocations Columns**

| Column Type                      | Description                                                                                                                                                                                                                                                                                       |
|----------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>name text</code>           | The name of the shared memory allocation. NULL for unused memory and <code>&lt;anonymous&gt;</code> for anonymous allocations.                                                                                                                                                                    |
| <code>off int8</code>            | The offset at which the allocation starts. NULL for anonymous allocations, since details related to them are not known.                                                                                                                                                                           |
| <code>size int8</code>           | Size of the allocation                                                                                                                                                                                                                                                                            |
| <code>allocated_size int8</code> | Size of the allocation including padding. For anonymous allocations, no information about padding is available, so the <code>size</code> and <code>allocated_size</code> columns will always be equal. Padding is not meaningful for free memory, so the columns will be equal in that case also. |

Anonymous allocations are allocations that have been made with `ShmemAlloc()` directly, rather than via `ShmemInitStruct()` or `ShmemInitHash()`.

By default, the `pg_shmem_allocations` view can be read only by superusers.

## 54.92. pg\_stats

The view `pg_stats` provides access to the information stored in the `pg_statistic` catalog. This view allows access only to rows of `pg_statistic` that correspond to tables the user has permission to read, and therefore it is safe to allow public read access to this view.

`pg_stats` is also designed to present the information in a more readable format than the underlying catalog — at the cost that its schema must be extended whenever new slot types are defined for `pg_statistic`.

**Table 54.93. pg\_stats Columns**

| Column Type                                                     | Description                          |
|-----------------------------------------------------------------|--------------------------------------|
| <code>schemaname name (references pg_namespace .nspname)</code> | Name of schema containing table      |
| <code>tablename name (references pg_class .relname)</code>      | Name of table                        |
| <code>attname name (references pg_attribute .attname)</code>    | Name of column described by this row |
| <code>inherited bool</code>                                     |                                      |

| Column Type                                  | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
|----------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                              | If true, this row includes inheritance child columns, not just the values in the specified table                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| <code>null_frac float4</code>                | Fraction of column entries that are null                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| <code>avg_width int4</code>                  | Average width in bytes of column's entries                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| <code>n_distinct float4</code>               | If greater than zero, the estimated number of distinct values in the column. If less than zero, the negative of the number of distinct values divided by the number of rows. (The negative form is used when <code>ANALYZE</code> believes that the number of distinct values is likely to increase as the table grows; the positive form is used when the column seems to have a fixed number of possible values.) For example, -1 indicates a unique column in which the number of distinct values is the same as the number of rows. |
| <code>most_common_vals anyarray</code>       | A list of the most common values in the column. (Null if no values seem to be more common than any others.)                                                                                                                                                                                                                                                                                                                                                                                                                             |
| <code>most_common_freqs float4[]</code>      | A list of the frequencies of the most common values, i.e., number of occurrences of each divided by total number of rows. (Null when <code>most_common_vals</code> is.)                                                                                                                                                                                                                                                                                                                                                                 |
| <code>histogram_bounds anyarray</code>       | A list of values that divide the column's values into groups of approximately equal population. The values in <code>most_common_vals</code> , if present, are omitted from this histogram calculation. (This column is null if the column data type does not have a <code>&lt;</code> operator or if the <code>most_common_vals</code> list accounts for the entire population.)                                                                                                                                                        |
| <code>correlation float4</code>              | Statistical correlation between physical row ordering and logical ordering of the column values. This ranges from -1 to +1. When the value is near -1 or +1, an index scan on the column will be estimated to be cheaper than when it is near zero, due to reduction of random access to the disk. (This column is null if the column data type does not have a <code>&lt;</code> operator.)                                                                                                                                            |
| <code>most_common_elems anyarray</code>      | A list of non-null element values most often appearing within values of the column. (Null for scalar types.)                                                                                                                                                                                                                                                                                                                                                                                                                            |
| <code>most_common_elem_freqs float4[]</code> | A list of the frequencies of the most common element values, i.e., the fraction of rows containing at least one instance of the given value. Two or three additional values follow the per-element frequencies; these are the minimum and maximum of the preceding per-element frequencies, and optionally the frequency of null elements. (Null when <code>most_common_elems</code> is.)                                                                                                                                               |
| <code>elem_count_histogram float4[]</code>   | A histogram of the counts of distinct non-null element values within the values of the column, followed by the average number of distinct non-null elements. (Null for scalar types.)                                                                                                                                                                                                                                                                                                                                                   |

The maximum number of entries in the array fields can be controlled on a column-by-column basis using the `ALTER TABLE SET STATISTICS` command, or globally by setting the `default_statistics_target` runtime parameter.

## 54.93. `pg_stats_ext`

The view `pg_stats_ext` provides access to information about each extended statistics object in the database, combining information stored in the `pg_statistic_ext` and `pg_statistic_ext_data` catalogs. This view allows access only to rows of `pg_statistic_ext` and `pg_statistic_ext_data` that correspond to tables the user owns, and therefore it is safe to allow public read access to this view.

`pg_stats_ext` is also designed to present the information in a more readable format than the underlying catalogs — at the cost that its schema must be extended whenever new types of extended statistics are added to `pg_statistic_ext`.

**Table 54.94. `pg_stats_ext` Columns**

| Column Type                                                                              | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |

| <code>n_distinct pg_ndistinct</code>                                                     | N-distinct counts for combinations of column values. If greater than zero, the estimated number of distinct values in the combination. If less than zero, the negative of the number of distinct values divided by the number of rows. (The negated form is used when <code>ANALYZE</code> believes that the number of distinct values is likely to increase as the table grows; the positive form is used when the column seems to have a fixed number of possible values.) For example, -1 indicates a unique combination of columns in which the number of distinct combinations is the same as the number of rows. |

| <code>most_common_vals text[]</code>                                                     | A list of the most common combinations of values in the columns. (Null if no combinations seem to be more common than any others.)                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| <code>most_common_val_nulls bool[]</code>                                                | A list of NULL flags for the most common combinations of values. (Null when <code>most_common_vals</code> is.)                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| <code>most_common_freqs float8[]</code>                                                  | A list of the frequencies of the most common combinations, i.e., number of occurrences of each divided by total number of rows. (Null when <code>most_common_vals</code> is.)                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| <code>most_common_base_freqs float8[]</code>                                             | A list of the base frequencies of the most common combinations, i.e., product of per-value frequencies. (Null when <code>most_common_vals</code> is.)                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |

The maximum number of entries in the array fields can be controlled on a column-by-column basis using the `ALTER TABLE SET STATISTICS` command, or globally by setting the `default_statistics_target` run-time parameter.

## 54.94. `pg_stats_ext_exprs`

The view `pg_stats_ext_exprs` provides access to information about all expressions included in extended statistics objects, combining information stored in the `pg_statistic_ext` and `pg_statistic_ext_data` catalogs. This view allows access only to rows of `pg_statistic_ext` and `pg_statistic_ext_data` that correspond to tables the user owns, and therefore it is safe to allow public read access to this view.

`pg_stats_ext_exprs` is also designed to present the information in a more readable format than the underlying catalogs — at the cost that its schema must be extended whenever the structure of statistics in `pg_statistic_ext` changes.

**Table 54.95. `pg_stats_ext_exprs` Columns**

| Column Type                                                                              | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |

| <code>null_frac float4</code>                                                            | Fraction of expression entries that are null                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| <code>avg_width int4</code>                                                              | Average width in bytes of expression's entries                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| <code>n_distinct float4</code>                                                           | If greater than zero, the estimated number of distinct values in the expression. If less than zero, the negative of the number of distinct values divided by the number of rows. (The negated form is used when <code>ANALYZE</code> believes that the number of distinct values is likely to increase as the table grows; the positive form is used when the expression seems to have a fixed number of possible values.) For example, -1 indicates a unique expression in which the number of distinct values is the same as the number of rows. |
| <code>most_common_vals anyarray</code>                                                   | A list of the most common values in the expression. (Null if no values seem to be more common than any others.)                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| <code>most_common_freqs float4[]</code>                                                  | A list of the frequencies of the most common values, i.e., number of occurrences of each divided by total number of rows. (Null when <code>most_common_vals</code> is.)                                                                                                                                                                                                                                                                                                                                                                            |
| <code>histogram_bounds anyarray</code>                                                   | A list of values that divide the expression's values into groups of approximately equal population. The values in <code>most_common_vals</code> , if present, are omitted from this histogram calculation. (This expression is null if the expression data type does not have a < operator or if the <code>most_common_vals</code> list accounts for the entire population.)                                                                                                                                                                       |
| <code>correlation float4</code>                                                          | Statistical correlation between physical row ordering and logical ordering of the expression values. This ranges from -1 to +1. When the value is near -1 or +1, an index scan on the expression will be estimated to be cheaper than when it is near zero, due to reduction of random access to the disk. (This expression is null if the expression's data type does not have a < operator.)                                                                                                                                                     |

| Column Type                                  | Description                                                                                                                                                                                                                                                                                                                                                                               |
|----------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>most_common_elems anyarray</code>      | A list of non-null element values most often appearing within values of the expression. (Null for scalar types.)                                                                                                                                                                                                                                                                          |
| <code>most_common_elem_freqs float4[]</code> | A list of the frequencies of the most common element values, i.e., the fraction of rows containing at least one instance of the given value. Two or three additional values follow the per-element frequencies; these are the minimum and maximum of the preceding per-element frequencies, and optionally the frequency of null elements. (Null when <code>most_common_elems</code> is.) |
| <code>elem_count_histogram float4[]</code>   | A histogram of the counts of distinct non-null element values within the values of the expression, followed by the average number of distinct non-null elements. (Null for scalar types.)                                                                                                                                                                                                 |

The maximum number of entries in the array fields can be controlled on a column-by-column basis using the `ALTER TABLE SET STATISTICS` command, or globally by setting the `default_statistics_target` run-time parameter.

## 54.95. pg\_tables

The view `pg_tables` provides access to useful information about each table in the database.

**Table 54.96. pg\_tables Columns**

| Column Type                                                         | Description                                                        |
|---------------------------------------------------------------------|--------------------------------------------------------------------|
| <code>schemaname name (references pg_namespace .nspname)</code>     | Name of schema containing table                                    |
| <code>tablename name (references pg_class .relname)</code>          | Name of table                                                      |
| <code>tableowner name (references pg_authid .rolname)</code>        | Name of table's owner                                              |
| <code>tablespace name (references pg_tablespace .spcname)</code>    | Name of tablespace containing table (null if default for database) |
| <code>hasindexes bool (references pg_class .relhasindex)</code>     | True if table has (or recently had) any indexes                    |
| <code>hasrules bool (references pg_class .relhasrules)</code>       | True if table has (or once had) rules                              |
| <code>hastriggers bool (references pg_class .relhastriggers)</code> | True if table has (or once had) triggers                           |
| <code>rowsecurity bool (references pg_class .relrowsecurity)</code> | True if row security is enabled on the table                       |

## 54.96. pg\_timezone\_abbrevs

The view `pg_timezone_abbrevs` provides a list of time zone abbreviations that are currently recognized by the datetime input routines. The contents of this view change when the `timezone_abbreviations` run-time parameter is modified.

**Table 54.97. pg\_timezone\_abbrevs Columns**

| Column Type              | Description |
|--------------------------|-------------|
| <code>abbrev text</code> |             |

| Column Type         | Description                                        |
|---------------------|----------------------------------------------------|
|                     | Time zone abbreviation                             |
| utc_offset interval | Offset from UTC (positive means east of Greenwich) |
| is_dst bool         | True if this is a daylight-savings abbreviation    |

While most timezone abbreviations represent fixed offsets from UTC, there are some that have historically varied in value (see [Section B.4](#) for more information). In such cases this view presents their current meaning.

## 54.97. pg\_timezone\_names

The view `pg_timezone_names` provides a list of time zone names that are recognized by `SET TIMEZONE`, along with their associated abbreviations, UTC offsets, and daylight-savings status. (Technically, Postgres Pro does not use UTC because leap seconds are not handled.) Unlike the abbreviations shown in `pg_timezone_abbrevs`, many of these names imply a set of daylight-savings transition date rules. Therefore, the associated information changes across local DST boundaries. The displayed information is computed based on the current value of `CURRENT_TIMESTAMP`.

**Table 54.98. pg\_timezone\_names Columns**

| Column Type         | Description                                        |
|---------------------|----------------------------------------------------|
| name text           | Time zone name                                     |
| abbrev text         | Time zone abbreviation                             |
| utc_offset interval | Offset from UTC (positive means east of Greenwich) |
| is_dst bool         | True if currently observing daylight savings       |

## 54.98. pg\_user

The view `pg_user` provides access to information about database users. This is simply a publicly readable view of `pg_shadow` that blanks out the password field.

**Table 54.99. pg\_user Columns**

| Column Type      | Description                                                                           |
|------------------|---------------------------------------------------------------------------------------|
| username name    | User name                                                                             |
| usesysid oid     | ID of this user                                                                       |
| usecreatedb bool | User can create databases                                                             |
| usesuper bool    | User is a superuser                                                                   |
| userepl bool     | User can initiate streaming replication and put the system in and out of backup mode. |

| Column Type                      | Description                                                                                          |
|----------------------------------|------------------------------------------------------------------------------------------------------|
| <code>usebypassrls bool</code>   | User bypasses every row-level security policy, see <a href="#">Section 5.8</a> for more information. |
| <code>passwd text</code>         | Not the password (always reads as <code>*****</code> )                                               |
| <code>valuntil timestampz</code> | Password expiry time (only used for password authentication)                                         |
| <code>useconfig text[]</code>    | Session defaults for run-time configuration variables                                                |

## 54.99. `pg_user_mappings`

The view `pg_user_mappings` provides access to information about user mappings. This is essentially a publicly readable view of `pg_user_mapping` that leaves out the options field if the user has no rights to use it.

**Table 54.100. `pg_user_mappings` Columns**

| Column Type                                                                    | Description                                                               |
|--------------------------------------------------------------------------------|---------------------------------------------------------------------------|
| <code>umid oid (references <code>pg_user_mapping</code> .oid)</code>           | OID of the user mapping                                                   |
| <code>srvid oid (references <code>pg_foreign_server</code> .oid)</code>        | The OID of the foreign server that contains this mapping                  |
| <code>srvname name (references <code>pg_foreign_server</code> .srvname)</code> | Name of the foreign server                                                |
| <code>umuser oid (references <code>pg_authid</code> .oid)</code>               | OID of the local role being mapped, or zero if the user mapping is public |
| <code>username name</code>                                                     | Name of the local user to be mapped                                       |
| <code>umoptions text[]</code>                                                  | User mapping specific options, as “keyword=value” strings                 |

To protect password information stored as a user mapping option, the `umoptions` column will read as null unless one of the following applies:

- current user is the user being mapped, and owns the server or holds `USAGE` privilege on it
- current user is the server owner and mapping is for `PUBLIC`
- current user is a superuser

## 54.100. `pg_views`

The view `pg_views` provides access to useful information about each view in the database.

**Table 54.101. `pg_views` Columns**

| Column Type                                                                  | Description                    |
|------------------------------------------------------------------------------|--------------------------------|
| <code>schemaname name (references <code>pg_namespace</code> .nspname)</code> | Name of schema containing view |
| <code>viewname name (references <code>pg_class</code> .relname)</code>       | Name of view                   |

| Column Type                                                 | Description                                                 |
|-------------------------------------------------------------|-------------------------------------------------------------|
| viewowner name (references <code>pg_authid</code> .rolname) | Name of view's owner                                        |
| definition text                                             | View definition (a reconstructed <code>SELECT</code> query) |

---

# Chapter 55. Frontend/Backend Protocol

Postgres Pro uses a message-based protocol for communication between frontends and backends (clients and servers). The protocol is supported over TCP/IP and also over Unix-domain sockets. Port number 5432 has been registered with IANA as the customary TCP port number for servers supporting this protocol, but in practice any non-privileged port number can be used.

This document describes version 3.0 of the protocol, implemented in PostgreSQL 7.4 and later. For descriptions of the earlier protocol versions, see previous releases of the PostgreSQL documentation. A single server can support multiple protocol versions. The initial startup-request message tells the server which protocol version the client is attempting to use. If the major version requested by the client is not supported by the server, the connection will be rejected (for example, this would occur if the client requested protocol version 4.0, which does not exist as of this writing). If the minor version requested by the client is not supported by the server (e.g., the client requests version 3.1, but the server supports only 3.0), the server may either reject the connection or may respond with a `NegotiateProtocolVersion` message containing the highest minor protocol version which it supports. The client may then choose either to continue with the connection using the specified protocol version or to abort the connection.

In order to serve multiple clients efficiently, the server launches a new “backend” process for each client. In the current implementation, a new child process is created immediately after an incoming connection is detected. This is transparent to the protocol, however. For purposes of the protocol, the terms “backend” and “server” are interchangeable; likewise “frontend” and “client” are interchangeable.

## 55.1. Overview

The protocol has separate phases for startup and normal operation. In the startup phase, the frontend opens a connection to the server and authenticates itself to the satisfaction of the server. (This might involve a single message, or multiple messages depending on the authentication method being used.) If all goes well, the server then sends status information to the frontend, and finally enters normal operation. Except for the initial startup-request message, this part of the protocol is driven by the server.

During normal operation, the frontend sends queries and other commands to the backend, and the backend sends back query results and other responses. There are a few cases (such as `NOTIFY`) wherein the backend will send unsolicited messages, but for the most part this portion of a session is driven by frontend requests.

Termination of the session is normally by frontend choice, but can be forced by the backend in certain cases. In any case, when the backend closes the connection, it will roll back any open (incomplete) transaction before exiting.

Within normal operation, SQL commands can be executed through either of two sub-protocols. In the “simple query” protocol, the frontend just sends a textual query string, which is parsed and immediately executed by the backend. In the “extended query” protocol, processing of queries is separated into multiple steps: parsing, binding of parameter values, and execution. This offers flexibility and performance benefits, at the cost of extra complexity.

Normal operation has additional sub-protocols for special operations such as `COPY`.

### 55.1.1. Messaging Overview

All communication is through a stream of messages. The first byte of a message identifies the message type, and the next four bytes specify the length of the rest of the message (this length count includes itself, but not the message-type byte). The remaining contents of the message are determined by the message type. For historical reasons, the very first message sent by the client (the startup message) has no initial message-type byte.

To avoid losing synchronization with the message stream, both servers and clients typically read an entire message into a buffer (using the byte count) before attempting to process its contents. This allows easy recovery if an error is detected while processing the contents. In extreme situations (such as not

having enough memory to buffer the message), the receiver can use the byte count to determine how much input to skip before it resumes reading messages.

Conversely, both servers and clients must take care never to send an incomplete message. This is commonly done by marshaling the entire message in a buffer before beginning to send it. If a communications failure occurs partway through sending or receiving a message, the only sensible response is to abandon the connection, since there is little hope of recovering message-boundary synchronization.

### 55.1.2. Extended Query Overview

In the extended-query protocol, execution of SQL commands is divided into multiple steps. The state retained between steps is represented by two types of objects: *prepared statements* and *portals*. A prepared statement represents the result of parsing and semantic analysis of a textual query string. A prepared statement is not in itself ready to execute, because it might lack specific values for *parameters*. A portal represents a ready-to-execute or already-partially-executed statement, with any missing parameter values filled in. (For `SELECT` statements, a portal is equivalent to an open cursor, but we choose to use a different term since cursors don't handle non-`SELECT` statements.)

The overall execution cycle consists of a *parse* step, which creates a prepared statement from a textual query string; a *bind* step, which creates a portal given a prepared statement and values for any needed parameters; and an *execute* step that runs a portal's query. In the case of a query that returns rows (`SELECT`, `SHOW`, etc), the execute step can be told to fetch only a limited number of rows, so that multiple execute steps might be needed to complete the operation.

The backend can keep track of multiple prepared statements and portals (but note that these exist only within a session, and are never shared across sessions). Existing prepared statements and portals are referenced by names assigned when they were created. In addition, an “unnamed” prepared statement and portal exist. Although these behave largely the same as named objects, operations on them are optimized for the case of executing a query only once and then discarding it, whereas operations on named objects are optimized on the expectation of multiple uses.

### 55.1.3. Formats and Format Codes

Data of a particular data type might be transmitted in any of several different *formats*. As of PostgreSQL 7.4 the only supported formats are “text” and “binary”, but the protocol makes provision for future extensions. The desired format for any value is specified by a *format code*. Clients can specify a format code for each transmitted parameter value and for each column of a query result. Text has format code zero, binary has format code one, and all other format codes are reserved for future definition.

The text representation of values is whatever strings are produced and accepted by the input/output conversion functions for the particular data type. In the transmitted representation, there is no trailing null character; the frontend must add one to received values if it wants to process them as C strings. (The text format does not allow embedded nulls, by the way.)

Binary representations for integers use network byte order (most significant byte first). For other data types consult the documentation to learn about the binary representation. Keep in mind that binary representations for complex data types might change across server versions; the text format is usually the more portable choice.

## 55.2. Message Flow

This section describes the message flow and the semantics of each message type. (Details of the exact representation of each message appear in [Section 55.7](#).) There are several different sub-protocols depending on the state of the connection: start-up, query, function call, `COPY`, and termination. There are also special provisions for asynchronous operations (including notification responses and command cancellation), which can occur at any time after the start-up phase.

### 55.2.1. Start-up

To begin a session, a frontend opens a connection to the server and sends a startup message. This message includes the names of the user and of the database the user wants to connect to; it also identifies the

particular protocol version to be used. (Optionally, the startup message can include additional settings for run-time parameters.) The server then uses this information and the contents of its configuration files (such as `pg_hba.conf`) to determine whether the connection is provisionally acceptable, and what additional authentication is required (if any).

The server then sends an appropriate authentication request message, to which the frontend must reply with an appropriate authentication response message (such as a password). For all authentication methods except GSSAPI, SSPI and SASL, there is at most one request and one response. In some methods, no response at all is needed from the frontend, and so no authentication request occurs. For GSSAPI, SSPI and SASL, multiple exchanges of packets may be needed to complete the authentication.

The authentication cycle ends with the server either rejecting the connection attempt (`ErrorResponse`), or sending `AuthenticationOk`.

The possible messages from the server in this phase are:

#### `ErrorResponse`

The connection attempt has been rejected. The server then immediately closes the connection.

#### `AuthenticationOk`

The authentication exchange is successfully completed.

#### `AuthenticationKerberosV5`

The frontend must now take part in a Kerberos V5 authentication dialog (not described here, part of the Kerberos specification) with the server. If this is successful, the server responds with an `AuthenticationOk`, otherwise it responds with an `ErrorResponse`. This is no longer supported.

#### `AuthenticationCleartextPassword`

The frontend must now send a `PasswordMessage` containing the password in clear-text form. If this is the correct password, the server responds with an `AuthenticationOk`, otherwise it responds with an `ErrorResponse`.

#### `AuthenticationMD5Password`

The frontend must now send a `PasswordMessage` containing the password (with user name) encrypted via MD5, then encrypted again using the 4-byte random salt specified in the `AuthenticationMD5Password` message. If this is the correct password, the server responds with an `AuthenticationOk`, otherwise it responds with an `ErrorResponse`. The actual `PasswordMessage` can be computed in SQL as `concat('md5', md5(concat(md5(concat(password, username)), random-salt)))`. (Keep in mind the `md5()` function returns its result as a hex string.)

#### `AuthenticationSCMCredential`

This response is only possible for local Unix-domain connections on platforms that support SCM credential messages. The frontend must issue an SCM credential message and then send a single data byte. (The contents of the data byte are uninteresting; it's only used to ensure that the server waits long enough to receive the credential message.) If the credential is acceptable, the server responds with an `AuthenticationOk`, otherwise it responds with an `ErrorResponse`. (This message type is only issued by pre-9.1 servers. It may eventually be removed from the protocol specification.)

#### `AuthenticationGSS`

The frontend must now initiate a GSSAPI negotiation. The frontend will send a `GSSResponse` message with the first part of the GSSAPI data stream in response to this. If further messages are needed, the server will respond with `AuthenticationGSSContinue`.

#### `AuthenticationSSPI`

The frontend must now initiate an SSPI negotiation. The frontend will send a `GSSResponse` with the first part of the SSPI data stream in response to this. If further messages are needed, the server will respond with `AuthenticationGSSContinue`.

### AuthenticationGSSContinue

This message contains the response data from the previous step of GSSAPI or SSPI negotiation (AuthenticationGSS, AuthenticationSSPI or a previous AuthenticationGSSContinue). If the GSSAPI or SSPI data in this message indicates more data is needed to complete the authentication, the frontend must send that data as another GSSResponse message. If GSSAPI or SSPI authentication is completed by this message, the server will next send AuthenticationOk to indicate successful authentication or ErrorResponse to indicate failure.

### AuthenticationSASL

The frontend must now initiate a SASL negotiation, using one of the SASL mechanisms listed in the message. The frontend will send a SASLInitialResponse with the name of the selected mechanism, and the first part of the SASL data stream in response to this. If further messages are needed, the server will respond with AuthenticationSASLContinue. See [Section 55.3](#) for details.

### AuthenticationSASLContinue

This message contains challenge data from the previous step of SASL negotiation (AuthenticationSASL, or a previous AuthenticationSASLContinue). The frontend must respond with a SASLResponse message.

### AuthenticationSASLFinal

SASL authentication has completed with additional mechanism-specific data for the client. The server will next send AuthenticationOk to indicate successful authentication, or an ErrorResponse to indicate failure. This message is sent only if the SASL mechanism specifies additional data to be sent from server to client at completion.

### NegotiateProtocolVersion

The server does not support the minor protocol version requested by the client, but does support an earlier version of the protocol; this message indicates the highest supported minor version. This message will also be sent if the client requested unsupported protocol options (i.e., beginning with `_pq_`) in the startup packet. This message will be followed by an ErrorResponse or a message indicating the success or failure of authentication.

If the frontend does not support the authentication method requested by the server, then it should immediately close the connection.

After having received AuthenticationOk, the frontend must wait for further messages from the server. In this phase a backend process is being started, and the frontend is just an interested bystander. It is still possible for the startup attempt to fail (ErrorResponse) or the server to decline support for the requested minor protocol version (NegotiateProtocolVersion), but in the normal case the backend will send some ParameterStatus messages, BackendKeyData, and finally ReadyForQuery.

During this phase the backend will attempt to apply any additional run-time parameter settings that were given in the startup message. If successful, these values become session defaults. An error causes ErrorResponse and exit.

The possible messages from the backend in this phase are:

#### BackendKeyData

This message provides secret-key data that the frontend must save if it wants to be able to issue cancel requests later. The frontend should not respond to this message, but should continue listening for a ReadyForQuery message.

#### ParameterStatus

This message informs the frontend about the current (initial) setting of backend parameters, such as [client\\_encoding](#) or [DateStyle](#). The frontend can ignore this message, or record the settings for its future use; see [Section 55.2.7](#) for more details. The frontend should not respond to this message, but should continue listening for a ReadyForQuery message.

**ReadyForQuery**

Start-up is completed. The frontend can now issue commands.

**ErrorResponse**

Start-up failed. The connection is closed after sending this message.

**NoticeResponse**

A warning message has been issued. The frontend should display the message but continue listening for ReadyForQuery or ErrorResponse.

The ReadyForQuery message is the same one that the backend will issue after each command cycle. Depending on the coding needs of the frontend, it is reasonable to consider ReadyForQuery as starting a command cycle, or to consider ReadyForQuery as ending the start-up phase and each subsequent command cycle.

## 55.2.2. Simple Query

A simple query cycle is initiated by the frontend sending a Query message to the backend. The message includes an SQL command (or commands) expressed as a text string. The backend then sends one or more response messages depending on the contents of the query command string, and finally a ReadyForQuery response message. ReadyForQuery informs the frontend that it can safely send a new command. (It is not actually necessary for the frontend to wait for ReadyForQuery before issuing another command, but the frontend must then take responsibility for figuring out what happens if the earlier command fails and already-issued later commands succeed.)

The possible response messages from the backend are:

**CommandComplete**

An SQL command completed normally.

**CopyInResponse**

The backend is ready to copy data from the frontend to a table; see [Section 55.2.6](#).

**CopyOutResponse**

The backend is ready to copy data from a table to the frontend; see [Section 55.2.6](#).

**RowDescription**

Indicates that rows are about to be returned in response to a `SELECT`, `FETCH`, etc query. The contents of this message describe the column layout of the rows. This will be followed by a DataRow message for each row being returned to the frontend.

**DataRow**

One of the set of rows returned by a `SELECT`, `FETCH`, etc query.

**EmptyQueryResponse**

An empty query string was recognized.

**ErrorResponse**

An error has occurred.

**ReadyForQuery**

Processing of the query string is complete. A separate message is sent to indicate this because the query string might contain multiple SQL commands. (CommandComplete marks the end of processing one SQL command, not the whole string.) ReadyForQuery will always be sent, whether processing terminates successfully or with an error.

## NoticeResponse

A warning message has been issued in relation to the query. Notices are in addition to other responses, i.e., the backend will continue processing the command.

The response to a `SELECT` query (or other queries that return row sets, such as `EXPLAIN` or `SHOW`) normally consists of `RowDescription`, zero or more `DataRow` messages, and then `CommandComplete`. `COPY` to or from the frontend invokes special protocol as described in [Section 55.2.6](#). All other query types normally produce only a `CommandComplete` message.

Since a query string could contain several queries (separated by semicolons), there might be several such response sequences before the backend finishes processing the query string. `ReadyForQuery` is issued when the entire string has been processed and the backend is ready to accept a new query string.

If a completely empty (no contents other than whitespace) query string is received, the response is `EmptyQueryResponse` followed by `ReadyForQuery`.

In the event of an error, `ErrorResponse` is issued followed by `ReadyForQuery`. All further processing of the query string is aborted by `ErrorResponse` (even if more queries remained in it). Note that this might occur partway through the sequence of messages generated by an individual query.

In simple Query mode, the format of retrieved values is always text, except when the given command is a `FETCH` from a cursor declared with the `BINARY` option. In that case, the retrieved values are in binary format. The format codes given in the `RowDescription` message tell which format is being used.

A frontend must be prepared to accept `ErrorResponse` and `NoticeResponse` messages whenever it is expecting any other type of message. See also [Section 55.2.7](#) concerning messages that the backend might generate due to outside events.

Recommended practice is to code frontends in a state-machine style that will accept any message type at any time that it could make sense, rather than wiring in assumptions about the exact sequence of messages.

### 55.2.2.1. Multiple Statements in a Simple Query

When a simple Query message contains more than one SQL statement (separated by semicolons), those statements are executed as a single transaction, unless explicit transaction control commands are included to force a different behavior. For example, if the message contains

```
INSERT INTO mytable VALUES(1);
SELECT 1/0;
INSERT INTO mytable VALUES(2);
```

then the divide-by-zero failure in the `SELECT` will force rollback of the first `INSERT`. Furthermore, because execution of the message is abandoned at the first error, the second `INSERT` is never attempted at all.

If instead the message contains

```
BEGIN;
INSERT INTO mytable VALUES(1);
COMMIT;
INSERT INTO mytable VALUES(2);
SELECT 1/0;
```

then the first `INSERT` is committed by the explicit `COMMIT` command. The second `INSERT` and the `SELECT` are still treated as a single transaction, so that the divide-by-zero failure will roll back the second `INSERT`, but not the first one.

This behavior is implemented by running the statements in a multi-statement Query message in an *implicit transaction block* unless there is some explicit transaction block for them to run in. The main difference between an implicit transaction block and a regular one is that an implicit block is closed automatically at the end of the Query message, either by an implicit commit if there was no error, or an implicit rollback if there was an error. This is similar to the implicit commit or rollback that happens for a statement executed by itself (when not in a transaction block).

If the session is already in a transaction block, as a result of a `BEGIN` in some previous message, then the Query message simply continues that transaction block, whether the message contains one statement or several. However, if the Query message contains a `COMMIT` or `ROLLBACK` closing the existing transaction block, then any following statements are executed in an implicit transaction block. Conversely, if a `BEGIN` appears in a multi-statement Query message, then it starts a regular transaction block that will only be terminated by an explicit `COMMIT` or `ROLLBACK`, whether that appears in this Query message or a later one. If the `BEGIN` follows some statements that were executed as an implicit transaction block, those statements are not immediately committed; in effect, they are retroactively included into the new regular transaction block.

A `COMMIT` or `ROLLBACK` appearing in an implicit transaction block is executed as normal, closing the implicit block; however, a warning will be issued since a `COMMIT` or `ROLLBACK` without a previous `BEGIN` might represent a mistake. If more statements follow, a new implicit transaction block will be started for them.

Savepoints are not allowed in an implicit transaction block, since they would conflict with the behavior of automatically closing the block upon any error.

Remember that, regardless of any transaction control commands that may be present, execution of the Query message stops at the first error. Thus for example given

```
BEGIN;  
SELECT 1/0;  
ROLLBACK;
```

in a single Query message, the session will be left inside a failed regular transaction block, since the `ROLLBACK` is not reached after the divide-by-zero error. Another `ROLLBACK` will be needed to restore the session to a usable state.

Another behavior of note is that initial lexical and syntactic analysis is done on the entire query string before any of it is executed. Thus simple errors (such as a misspelled keyword) in later statements can prevent execution of any of the statements. This is normally invisible to users since the statements would all roll back anyway when done as an implicit transaction block. However, it can be visible when attempting to do multiple transactions within a multi-statement Query. For instance, if a typo turned our previous example into

```
BEGIN;  
INSERT INTO mytable VALUES(1);  
COMMIT;  
INSERT INTO mytable VALUES(2);  
SELCT 1/0;
```

then none of the statements would get run, resulting in the visible difference that the first `INSERT` is not committed. Errors detected at semantic analysis or later, such as a misspelled table or column name, do not have this effect.

Lastly, note that all the statements within the Query message will observe the same value of `statement_timestamp()`, since that timestamp is updated only upon receipt of the Query message. This will result in them all observing the same value of `transaction_timestamp()` as well, except in cases where the query string ends a previously-started transaction and begins a new one.

### 55.2.3. Extended Query

The extended query protocol breaks down the above-described simple query protocol into multiple steps. The results of preparatory steps can be re-used multiple times for improved efficiency. Furthermore, additional features are available, such as the possibility of supplying data values as separate parameters instead of having to insert them directly into a query string.

In the extended protocol, the frontend first sends a Parse message, which contains a textual query string, optionally some information about data types of parameter placeholders, and the name of a destination prepared-statement object (an empty string selects the unnamed prepared statement). The response is

either `ParseComplete` or `ErrorResponse`. Parameter data types can be specified by OID; if not given, the parser attempts to infer the data types in the same way as it would do for untyped literal string constants.

### Note

A parameter data type can be left unspecified by setting it to zero, or by making the array of parameter type OIDs shorter than the number of parameter symbols ( $\$n$ ) used in the query string. Another special case is that a parameter's type can be specified as `void` (that is, the OID of the `void` pseudo-type). This is meant to allow parameter symbols to be used for function parameters that are actually OUT parameters. Ordinarily there is no context in which a `void` parameter could be used, but if such a parameter symbol appears in a function's parameter list, it is effectively ignored. For example, a function call such as `foo($1, $2, $3, $4)` could match a function with two IN and two OUT arguments, if `$3` and `$4` are specified as having type `void`.

### Note

The query string contained in a `Parse` message cannot include more than one SQL statement; else a syntax error is reported. This restriction does not exist in the simple-query protocol, but it does exist in the extended protocol, because allowing prepared statements or portals to contain multiple commands would complicate the protocol unduly.

If successfully created, a named prepared-statement object lasts till the end of the current session, unless explicitly destroyed. An unnamed prepared statement lasts only until the next `Parse` statement specifying the unnamed statement as destination is issued. (Note that a simple `Query` message also destroys the unnamed statement.) Named prepared statements must be explicitly closed before they can be redefined by another `Parse` message, but this is not required for the unnamed statement. Named prepared statements can also be created and accessed at the SQL command level, using `PREPARE` and `EXECUTE`.

Once a prepared statement exists, it can be readied for execution using a `Bind` message. The `Bind` message gives the name of the source prepared statement (empty string denotes the unnamed prepared statement), the name of the destination portal (empty string denotes the unnamed portal), and the values to use for any parameter placeholders present in the prepared statement. The supplied parameter set must match those needed by the prepared statement. (If you declared any `void` parameters in the `Parse` message, pass `NULL` values for them in the `Bind` message.) `Bind` also specifies the format to use for any data returned by the query; the format can be specified overall, or per-column. The response is either `BindComplete` or `ErrorResponse`.

### Note

The choice between text and binary output is determined by the format codes given in `Bind`, regardless of the SQL command involved. The `BINARY` attribute in cursor declarations is irrelevant when using extended query protocol.

Query planning typically occurs when the `Bind` message is processed. If the prepared statement has no parameters, or is executed repeatedly, the server might save the created plan and re-use it during subsequent `Bind` messages for the same prepared statement. However, it will do so only if it finds that a generic plan can be created that is not much less efficient than a plan that depends on the specific parameter values supplied. This happens transparently so far as the protocol is concerned.

If successfully created, a named portal object lasts till the end of the current transaction, unless explicitly destroyed. An unnamed portal is destroyed at the end of the transaction, or as soon as the next `Bind` statement specifying the unnamed portal as destination is issued. (Note that a simple `Query` message also destroys the unnamed portal.) Named portals must be explicitly closed before they can be redefined

by another Bind message, but this is not required for the unnamed portal. Named portals can also be created and accessed at the SQL command level, using `DECLARE CURSOR` and `FETCH`.

Once a portal exists, it can be executed using an Execute message. The Execute message specifies the portal name (empty string denotes the unnamed portal) and a maximum result-row count (zero meaning “fetch all rows”). The result-row count is only meaningful for portals containing commands that return row sets; in other cases the command is always executed to completion, and the row count is ignored. The possible responses to Execute are the same as those described above for queries issued via simple query protocol, except that Execute doesn't cause ReadyForQuery or RowDescription to be issued.

If Execute terminates before completing the execution of a portal (due to reaching a nonzero result-row count), it will send a PortalSuspended message; the appearance of this message tells the frontend that another Execute should be issued against the same portal to complete the operation. The CommandComplete message indicating completion of the source SQL command is not sent until the portal's execution is completed. Therefore, an Execute phase is always terminated by the appearance of exactly one of these messages: CommandComplete, EmptyQueryResponse (if the portal was created from an empty query string), ErrorResponse, or PortalSuspended.

At completion of each series of extended-query messages, the frontend should issue a Sync message. This parameterless message causes the backend to close the current transaction if it's not inside a `BEGIN/COMMIT` transaction block (“close” meaning to commit if no error, or roll back if error). Then a ReadyForQuery response is issued. The purpose of Sync is to provide a resynchronization point for error recovery. When an error is detected while processing any extended-query message, the backend issues ErrorResponse, then reads and discards messages until a Sync is reached, then issues ReadyForQuery and returns to normal message processing. (But note that no skipping occurs if an error is detected *while* processing Sync — this ensures that there is one and only one ReadyForQuery sent for each Sync.)

### Note

Sync does not cause a transaction block opened with `BEGIN` to be closed. It is possible to detect this situation since the ReadyForQuery message includes transaction status information.

In addition to these fundamental, required operations, there are several optional operations that can be used with extended-query protocol.

The Describe message (portal variant) specifies the name of an existing portal (or an empty string for the unnamed portal). The response is a RowDescription message describing the rows that will be returned by executing the portal; or a NoData message if the portal does not contain a query that will return rows; or ErrorResponse if there is no such portal.

The Describe message (statement variant) specifies the name of an existing prepared statement (or an empty string for the unnamed prepared statement). The response is a ParameterDescription message describing the parameters needed by the statement, followed by a RowDescription message describing the rows that will be returned when the statement is eventually executed (or a NoData message if the statement will not return rows). ErrorResponse is issued if there is no such prepared statement. Note that since Bind has not yet been issued, the formats to be used for returned columns are not yet known to the backend; the format code fields in the RowDescription message will be zeroes in this case.

### Tip

In most scenarios the frontend should issue one or the other variant of Describe before issuing Execute, to ensure that it knows how to interpret the results it will get back.

The Close message closes an existing prepared statement or portal and releases resources. It is not an error to issue Close against a nonexistent statement or portal name. The response is normally CloseComplete, but could be ErrorResponse if some difficulty is encountered while releasing resources. Note

that closing a prepared statement implicitly closes any open portals that were constructed from that statement.

The Flush message does not cause any specific output to be generated, but forces the backend to deliver any data pending in its output buffers. A Flush must be sent after any extended-query command except Sync, if the frontend wishes to examine the results of that command before issuing more commands. Without Flush, messages returned by the backend will be combined into the minimum possible number of packets to minimize network overhead.

### Note

The simple Query message is approximately equivalent to the series Parse, Bind, portal Describe, Execute, Close, Sync, using the unnamed prepared statement and portal objects and no parameters. One difference is that it will accept multiple SQL statements in the query string, automatically performing the bind/describe/execute sequence for each one in succession. Another difference is that it will not return ParseComplete, BindComplete, CloseComplete, or NoData messages.

## 55.2.4. Pipelining

Use of the extended query protocol allows *pipelining*, which means sending a series of queries without waiting for earlier ones to complete. This reduces the number of network round trips needed to complete a given series of operations. However, the user must carefully consider the required behavior if one of the steps fails, since later queries will already be in flight to the server.

One way to deal with that is to make the whole query series be a single transaction, that is wrap it in `BEGIN ... COMMIT`. However, this does not help if one wishes for some of the commands to commit independently of others.

The extended query protocol provides another way to manage this concern, which is to omit sending Sync messages between steps that are dependent. Since, after an error, the backend will skip command messages until it finds Sync, this allows later commands in a pipeline to be skipped automatically when an earlier one fails, without the client having to manage that explicitly with `BEGIN` and `COMMIT`. Independently-committable segments of the pipeline can be separated by Sync messages.

If the client has not issued an explicit `BEGIN`, then each Sync ordinarily causes an implicit `COMMIT` if the preceding step(s) succeeded, or an implicit `ROLLBACK` if they failed. However, there are a few DDL commands (such as `CREATE DATABASE`) that cannot be executed inside a transaction block. If one of these is executed in a pipeline, it will fail unless it is the first command in the pipeline. Furthermore, upon success it will force an immediate commit to preserve database consistency. Thus a Sync immediately following one of these commands has no effect except to respond with ReadyForQuery.

When using this method, completion of the pipeline must be determined by counting ReadyForQuery messages and waiting for that to reach the number of Syncs sent. Counting command completion responses is unreliable, since some of the commands may be skipped and thus not produce a completion message.

## 55.2.5. Function Call

The Function Call sub-protocol allows the client to request a direct call of any function that exists in the database's `pg_proc` system catalog. The client must have execute permission for the function.

### Note

The Function Call sub-protocol is a legacy feature that is probably best avoided in new code. Similar results can be accomplished by setting up a prepared statement that does `SELECT function($1, ...)`. The Function Call cycle can then be replaced with Bind/Execute.

A Function Call cycle is initiated by the frontend sending a `FunctionCall` message to the backend. The backend then sends one or more response messages depending on the results of the function call, and finally a `ReadyForQuery` response message. `ReadyForQuery` informs the frontend that it can safely send a new query or function call.

The possible response messages from the backend are:

`ErrorResponse`

An error has occurred.

`FunctionCallResponse`

The function call was completed and returned the result given in the message. (Note that the Function Call protocol can only handle a single scalar result, not a row type or set of results.)

`ReadyForQuery`

Processing of the function call is complete. `ReadyForQuery` will always be sent, whether processing terminates successfully or with an error.

`NoticeResponse`

A warning message has been issued in relation to the function call. Notices are in addition to other responses, i.e., the backend will continue processing the command.

## 55.2.6. COPY Operations

The `COPY` command allows high-speed bulk data transfer to or from the server. Copy-in and copy-out operations each switch the connection into a distinct sub-protocol, which lasts until the operation is completed.

Copy-in mode (data transfer to the server) is initiated when the backend executes a `COPY FROM STDIN` SQL statement. The backend sends a `CopyInResponse` message to the frontend. The frontend should then send zero or more `CopyData` messages, forming a stream of input data. (The message boundaries are not required to have anything to do with row boundaries, although that is often a reasonable choice.) The frontend can terminate the copy-in mode by sending either a `CopyDone` message (allowing successful termination) or a `CopyFail` message (which will cause the `COPY` SQL statement to fail with an error). The backend then reverts to the command-processing mode it was in before the `COPY` started, which will be either simple or extended query protocol. It will next send either `CommandComplete` (if successful) or `ErrorResponse` (if not).

In the event of a backend-detected error during copy-in mode (including receipt of a `CopyFail` message), the backend will issue an `ErrorResponse` message. If the `COPY` command was issued via an extended-query message, the backend will now discard frontend messages until a `Sync` message is received, then it will issue `ReadyForQuery` and return to normal processing. If the `COPY` command was issued in a simple Query message, the rest of that message is discarded and `ReadyForQuery` is issued. In either case, any subsequent `CopyData`, `CopyDone`, or `CopyFail` messages issued by the frontend will simply be dropped.

The backend will ignore `Flush` and `Sync` messages received during copy-in mode. Receipt of any other non-copy message type constitutes an error that will abort the copy-in state as described above. (The exception for `Flush` and `Sync` is for the convenience of client libraries that always send `Flush` or `Sync` after an `Execute` message, without checking whether the command to be executed is a `COPY FROM STDIN`.)

Copy-out mode (data transfer from the server) is initiated when the backend executes a `COPY TO STDOUT` SQL statement. The backend sends a `CopyOutResponse` message to the frontend, followed by zero or more `CopyData` messages (always one per row), followed by `CopyDone`. The backend then reverts to the command-processing mode it was in before the `COPY` started, and sends `CommandComplete`. The frontend cannot abort the transfer (except by closing the connection or issuing a `Cancel` request), but it can discard unwanted `CopyData` and `CopyDone` messages.

In the event of a backend-detected error during copy-out mode, the backend will issue an `ErrorResponse` message and revert to normal processing. The frontend should treat receipt of `ErrorResponse` as terminating the copy-out mode.

It is possible for `NoticeResponse` and `ParameterStatus` messages to be interspersed between `CopyData` messages; frontends must handle these cases, and should be prepared for other asynchronous message types as well (see [Section 55.2.7](#)). Otherwise, any message type other than `CopyData` or `CopyDone` may be treated as terminating copy-out mode.

There is another Copy-related mode called `copy-both`, which allows high-speed bulk data transfer to *and* from the server. `Copy-both` mode is initiated when a backend in `walsender` mode executes a `START_REPLICATION` statement. The backend sends a `CopyBothResponse` message to the frontend. Both the backend and the frontend may then send `CopyData` messages until either end sends a `CopyDone` message. After the client sends a `CopyDone` message, the connection goes from `copy-both` mode to `copy-out` mode, and the client may not send any more `CopyData` messages. Similarly, when the server sends a `CopyDone` message, the connection goes into `copy-in` mode, and the server may not send any more `CopyData` messages. After both sides have sent a `CopyDone` message, the copy mode is terminated, and the backend reverts to the command-processing mode. In the event of a backend-detected error during `copy-both` mode, the backend will issue an `ErrorResponse` message, discard frontend messages until a `Sync` message is received, and then issue `ReadyForQuery` and return to normal processing. The frontend should treat receipt of `ErrorResponse` as terminating the copy in both directions; no `CopyDone` should be sent in this case. See [Section 55.4](#) for more information on the subprotocol transmitted over `copy-both` mode.

The `CopyInResponse`, `CopyOutResponse` and `CopyBothResponse` messages include fields that inform the frontend of the number of columns per row and the format codes being used for each column. (As of the present implementation, all columns in a given `COPY` operation will use the same format, but the message design does not assume this.)

## 55.2.7. Asynchronous Operations

There are several cases in which the backend will send messages that are not specifically prompted by the frontend's command stream. Frontends must be prepared to deal with these messages at any time, even when not engaged in a query. At minimum, one should check for these cases before beginning to read a query response.

It is possible for `NoticeResponse` messages to be generated due to outside activity; for example, if the database administrator commands a “fast” database shutdown, the backend will send a `NoticeResponse` indicating this fact before closing the connection. Accordingly, frontends should always be prepared to accept and display `NoticeResponse` messages, even when the connection is nominally idle.

`ParameterStatus` messages will be generated whenever the active value changes for any of the parameters the backend believes the frontend should know about. Most commonly this occurs in response to a `SET SQL` command executed by the frontend, and this case is effectively synchronous — but it is also possible for parameter status changes to occur because the administrator changed a configuration file and then sent the `SIGHUP` signal to the server. Also, if a `SET` command is rolled back, an appropriate `ParameterStatus` message will be generated to report the current effective value.

At present there is a hard-wired set of parameters for which `ParameterStatus` will be generated: they are `server_version`, `server_encoding`, `client_encoding`, `application_name`, `default_transaction_read_only`, `in_hot_standby`, `is_superuser`, `session_authorization`, `DateStyle`, `IntervalStyle`, `TimeZone`, `integer_datetimes`, and `standard_conforming_strings`. (`server_encoding`, `TimeZone`, and `integer_datetimes` were not reported by releases before 8.0; `standard_conforming_strings` was not reported by releases before 8.1; `IntervalStyle` was not reported by releases before 8.4; `application_name` was not reported by releases before 9.0; `default_transaction_read_only` and `in_hot_standby` were not reported by releases before 14.) Note that `server_version`, `server_encoding` and `integer_datetimes` are pseudo-parameters that cannot change after startup. This set might change in the future, or even become configurable. Accordingly, a frontend should simply ignore `ParameterStatus` for parameters that it does not understand or care about.

If a frontend issues a `LISTEN` command, then the backend will send a `NotificationResponse` message (not to be confused with `NoticeResponse`!) whenever a `NOTIFY` command is executed for the same channel name.

### Note

At present, `NotificationResponse` can only be sent outside a transaction, and thus it will not occur in the middle of a command-response series, though it might occur just before `ReadyForQuery`. It is unwise to design frontend logic that assumes that, however. Good practice is to be able to accept `NotificationResponse` at any point in the protocol.

## 55.2.8. Canceling Requests in Progress

During the processing of a query, the frontend might request cancellation of the query. The cancel request is not sent directly on the open connection to the backend for reasons of implementation efficiency: we don't want to have the backend constantly checking for new input from the frontend during query processing. Cancel requests should be relatively infrequent, so we make them slightly cumbersome in order to avoid a penalty in the normal case.

To issue a cancel request, the frontend opens a new connection to the server and sends a `CancelRequest` message, rather than the `StartupMessage` message that would ordinarily be sent across a new connection. The server will process this request and then close the connection. For security reasons, no direct reply is made to the cancel request message.

A `CancelRequest` message will be ignored unless it contains the same key data (PID and secret key) passed to the frontend during connection start-up. If the request matches the PID and secret key for a currently executing backend, the processing of the current query is aborted. (In the existing implementation, this is done by sending a special signal to the backend process that is processing the query.)

The cancellation signal might or might not have any effect — for example, if it arrives after the backend has finished processing the query, then it will have no effect. If the cancellation is effective, it results in the current command being terminated early with an error message.

The upshot of all this is that for reasons of both security and efficiency, the frontend has no direct way to tell whether a cancel request has succeeded. It must continue to wait for the backend to respond to the query. Issuing a cancel simply improves the odds that the current query will finish soon, and improves the odds that it will fail with an error message instead of succeeding.

Since the cancel request is sent across a new connection to the server and not across the regular frontend/backend communication link, it is possible for the cancel request to be issued by any process, not just the frontend whose query is to be canceled. This might provide additional flexibility when building multiple-process applications. It also introduces a security risk, in that unauthorized persons might try to cancel queries. The security risk is addressed by requiring a dynamically generated secret key to be supplied in cancel requests.

## 55.2.9. Termination

The normal, graceful termination procedure is that the frontend sends a `Terminate` message and immediately closes the connection. On receipt of this message, the backend closes the connection and terminates.

In rare cases (such as an administrator-commanded database shutdown) the backend might disconnect without any frontend request to do so. In such cases the backend will attempt to send an error or notice message giving the reason for the disconnection before it closes the connection.

Other termination scenarios arise from various failure cases, such as core dump at one end or the other, loss of the communications link, loss of message-boundary synchronization, etc. If either frontend or backend sees an unexpected closure of the connection, it should clean up and terminate. The frontend

has the option of launching a new backend by recontacting the server if it doesn't want to terminate itself. Closing the connection is also advisable if an unrecognizable message type is received, since this probably indicates loss of message-boundary sync.

For either normal or abnormal termination, any open transaction is rolled back, not committed. One should note however that if a frontend disconnects while a non-`SELECT` query is being processed, the backend will probably finish the query before noticing the disconnection. If the query is outside any transaction block (`BEGIN ... COMMIT` sequence) then its results might be committed before the disconnection is recognized.

### 55.2.10. SSL Session Encryption

If Postgres Pro was built with SSL support, frontend/backend communications can be encrypted using SSL. This provides communication security in environments where attackers might be able to capture the session traffic. For more information on encrypting Postgres Pro sessions with SSL, see [Section 18.9](#).

To initiate an SSL-encrypted connection, the frontend initially sends an `SSLRequest` message rather than a `StartupMessage`. The server then responds with a single byte containing `S` or `N`, indicating that it is willing or unwilling to perform SSL, respectively. The frontend might close the connection at this point if it is dissatisfied with the response. To continue after `S`, perform an SSL startup handshake (not described here, part of the SSL specification) with the server. If this is successful, continue with sending the usual `StartupMessage`. In this case the `StartupMessage` and all subsequent data will be SSL-encrypted. To continue after `N`, send the usual `StartupMessage` and proceed without encryption. (Alternatively, it is permissible to issue a `GSSENCRequest` message after an `N` response to try to use GSSAPI encryption instead of SSL.)

The frontend should also be prepared to handle an `ErrorMessage` response to `SSLRequest` from the server. The frontend should not display this error message to the user/application, since the server has not been authenticated ([CVE-2024-10977](#)). In this case the connection must be closed, but the frontend might choose to open a fresh connection and proceed without requesting SSL.

When SSL encryption can be performed, the server is expected to send only the single `s` byte and then wait for the frontend to initiate an SSL handshake. If additional bytes are available to read at this point, it likely means that a man-in-the-middle is attempting to perform a buffer-stuffing attack ([CVE-2021-23222](#)). Frontends should be coded either to read exactly one byte from the socket before turning the socket over to their SSL library, or to treat it as a protocol violation if they find they have read additional bytes.

An initial `SSLRequest` can also be used in a connection that is being opened to send a `CancelRequest` message.

While the protocol itself does not provide a way for the server to force SSL encryption, the administrator can configure the server to reject unencrypted sessions as a byproduct of authentication checking.

### 55.2.11. GSSAPI Session Encryption

If Postgres Pro was built with GSSAPI support, frontend/backend communications can be encrypted using GSSAPI. This provides communication security in environments where attackers might be able to capture the session traffic. For more information on encrypting Postgres Pro sessions with GSSAPI, see [Section 18.10](#).

To initiate a GSSAPI-encrypted connection, the frontend initially sends a `GSSENCRequest` message rather than a `StartupMessage`. The server then responds with a single byte containing `G` or `N`, indicating that it is willing or unwilling to perform GSSAPI encryption, respectively. The frontend might close the connection at this point if it is dissatisfied with the response. To continue after `G`, using the GSSAPI C bindings as discussed in [RFC 2744](#) or equivalent, perform a GSSAPI initialization by calling `gss_init_sec_context()` in a loop and sending the result to the server, starting with an empty input and then with each result from the server, until it returns no output. When sending the results of `gss_init_sec_context()` to the server, prepend the length of the message as a four byte integer in network byte order. To continue after `N`, send the usual `StartupMessage` and proceed without encryption.

(Alternatively, it is permissible to issue an `SSLRequest` message after an `N` response to try to use SSL encryption instead of GSSAPI.)

The frontend should also be prepared to handle an `ErrorMessage` response to `GSSENCRequest` from the server. The frontend should not display this error message to the user/application, since the server has not been authenticated ([CVE-2024-10977](#)). In this case the connection must be closed, but the frontend might choose to open a fresh connection and proceed without requesting GSSAPI encryption.

When GSSAPI encryption can be performed, the server is expected to send only the single `G` byte and then wait for the frontend to initiate a GSSAPI handshake. If additional bytes are available to read at this point, it likely means that a man-in-the-middle is attempting to perform a buffer-stuffing attack ([CVE-2021-23222](#)). Frontends should be coded either to read exactly one byte from the socket before turning the socket over to their GSSAPI library, or to treat it as a protocol violation if they find they have read additional bytes.

An initial `GSSENCRequest` can also be used in a connection that is being opened to send a `CancelRequest` message.

Once GSSAPI encryption has been successfully established, use `gss_wrap()` to encrypt the usual `StartupMessage` and all subsequent data, prepending the length of the result from `gss_wrap()` as a four byte integer in network byte order to the actual encrypted payload. Note that the server will only accept encrypted packets from the client which are less than 16kB; `gss_wrap_size_limit()` should be used by the client to determine the size of the unencrypted message which will fit within this limit and larger messages should be broken up into multiple `gss_wrap()` calls. Typical segments are 8kB of unencrypted data, resulting in encrypted packets of slightly larger than 8kB but well within the 16kB maximum. The server can be expected to not send encrypted packets of larger than 16kB to the client.

While the protocol itself does not provide a way for the server to force GSSAPI encryption, the administrator can configure the server to reject unencrypted sessions as a byproduct of authentication checking.

## 55.3. SASL Authentication

SASL is a framework for authentication in connection-oriented protocols. At the moment, Postgres Pro implements two SASL authentication mechanisms, SCRAM-SHA-256 and SCRAM-SHA-256-PLUS. More might be added in the future. The below steps illustrate how SASL authentication is performed in general, while the next subsection gives more details on SCRAM-SHA-256 and SCRAM-SHA-256-PLUS.

### SASL Authentication Message Flow

1. To begin a SASL authentication exchange, the server sends an `AuthenticationSASL` message. It includes a list of SASL authentication mechanisms that the server can accept, in the server's preferred order.
2. The client selects one of the supported mechanisms from the list, and sends a `SASLInitialResponse` message to the server. The message includes the name of the selected mechanism, and an optional Initial Client Response, if the selected mechanism uses that.
3. One or more server-challenge and client-response message will follow. Each server-challenge is sent in an `AuthenticationSASLContinue` message, followed by a response from client in a `SASLResponse` message. The particulars of the messages are mechanism specific.
4. Finally, when the authentication exchange is completed successfully, the server sends an `AuthenticationSASLFinal` message, followed immediately by an `AuthenticationOk` message. The `AuthenticationSASLFinal` contains additional server-to-client data, whose content is particular to the selected authentication mechanism. If the authentication mechanism doesn't use additional data that's sent at completion, the `AuthenticationSASLFinal` message is not sent.

On error, the server can abort the authentication at any stage, and send an `ErrorMessage`.

### 55.3.1. SCRAM-SHA-256 Authentication

The implemented SASL mechanisms at the moment are `SCRAM-SHA-256` and its variant with channel binding `SCRAM-SHA-256-PLUS`. They are described in detail in [RFC 7677](#) and [RFC 5802](#).

When SCRAM-SHA-256 is used in Postgres Pro, the server will ignore the user name that the client sends in the `client-first-message`. The user name that was already sent in the startup message is used instead. Postgres Pro supports multiple character encodings, while SCRAM dictates UTF-8 to be used for the user name, so it might be impossible to represent the Postgres Pro user name in UTF-8.

The SCRAM specification dictates that the password is also in UTF-8, and is processed with the *SASLprep* algorithm. Postgres Pro, however, does not require UTF-8 to be used for the password. When a user's password is set, it is processed with SASLprep as if it was in UTF-8, regardless of the actual encoding used. However, if it is not a legal UTF-8 byte sequence, or it contains UTF-8 byte sequences that are prohibited by the SASLprep algorithm, the raw password will be used without SASLprep processing, instead of throwing an error. This allows the password to be normalized when it is in UTF-8, but still allows a non-UTF-8 password to be used, and doesn't require the system to know which encoding the password is in.

*Channel binding* is supported in Postgres Pro builds with SSL support. The SASL mechanism name for SCRAM with channel binding is `SCRAM-SHA-256-PLUS`. The channel binding type used by Postgres Pro is `tls-server-end-point`.

In SCRAM without channel binding, the server chooses a random number that is transmitted to the client to be mixed with the user-supplied password in the transmitted password hash. While this prevents the password hash from being successfully retransmitted in a later session, it does not prevent a fake server between the real server and client from passing through the server's random value and successfully authenticating.

SCRAM with channel binding prevents such man-in-the-middle attacks by mixing the signature of the server's certificate into the transmitted password hash. While a fake server can retransmit the real server's certificate, it doesn't have access to the private key matching that certificate, and therefore cannot prove it is the owner, causing SSL connection failure.

### Example

1. The server sends an `AuthenticationSASL` message. It includes a list of SASL authentication mechanisms that the server can accept. This will be `SCRAM-SHA-256-PLUS` and `SCRAM-SHA-256` if the server is built with SSL support, or else just the latter.
2. The client responds by sending a `SASLInitialResponse` message, which indicates the chosen mechanism, `SCRAM-SHA-256` or `SCRAM-SHA-256-PLUS`. (A client is free to choose either mechanism, but for better security it should choose the channel-binding variant if it can support it.) In the Initial Client response field, the message contains the SCRAM `client-first-message`. The `client-first-message` also contains the channel binding type chosen by the client.
3. Server sends an `AuthenticationSASLContinue` message, with a SCRAM `server-first-message` as the content.
4. Client sends a `SASLResponse` message, with SCRAM `client-final-message` as the content.
5. Server sends an `AuthenticationSASLFinal` message, with the SCRAM `server-final-message`, followed immediately by an `AuthenticationOk` message.

## 55.4. Streaming Replication Protocol

To initiate streaming replication, the frontend sends the `replication` parameter in the startup message. A Boolean value of `true` (or `on`, `yes`, `1`) tells the backend to go into physical replication walsender mode, wherein a small set of replication commands, shown below, can be issued instead of SQL statements.

Passing `database` as the value for the `replication` parameter instructs the backend to go into logical replication walsender mode, connecting to the database specified in the `dbname` parameter. In logical replication walsender mode, the replication commands shown below as well as normal SQL commands can be issued.

In either physical replication or logical replication walsender mode, only the simple query protocol can be used.

For the purpose of testing replication commands, you can make a replication connection via `psql` or any other libpq-using tool with a connection string including the `replication` option, e.g.:

```
psql "dbname=postgres replication=database" -c "IDENTIFY_SYSTEM;"
```

However, it is often more useful to use [pg\\_receivewal](#) (for physical replication) or [pg\\_recvlogical](#) (for logical replication).

Replication commands are logged in the server log when [log\\_replication\\_commands](#) is enabled.

The commands accepted in replication mode are:

`IDENTIFY_SYSTEM`

Requests the server to identify itself. Server replies with a result set of a single row, containing four fields:

`systemid (text)`

The unique system identifier identifying the cluster. This can be used to check that the base backup used to initialize the standby came from the same cluster.

`timeline (int4)`

Current timeline ID. Also useful to check that the standby is consistent with the primary.

`xlogpos (text)`

Current WAL flush location. Useful to get a known location in the write-ahead log where streaming can start.

`dbname (text)`

Database connected to or null.

`SHOW name`

Requests the server to send the current setting of a run-time parameter. This is similar to the SQL command [SHOW](#).

`name`

The name of a run-time parameter. Available parameters are documented in [Chapter 19](#).

`TIMELINE_HISTORY tli`

Requests the server to send over the timeline history file for timeline `tli`. Server replies with a result set of a single row, containing two fields. While the fields are labeled as `text`, they effectively return raw bytes, with no encoding conversion:

`filename (text)`

File name of the timeline history file, e.g., `00000002.history`.

`content (text)`

Contents of the timeline history file.

`CREATE_REPLICATION_SLOT slot_name [ TEMPORARY ] { PHYSICAL [ RESERVE_WAL ] | LOGICAL output_plugin [ EXPORT_SNAPSHOT | NOEXPORT_SNAPSHOT | USE_SNAPSHOT ] }`

Create a physical or logical replication slot. See [Section 26.2.6](#) for more about replication slots.

`slot_name`

The name of the slot to create. Must be a valid replication slot name (see [Section 26.2.6.1](#)).

*output\_plugin*

The name of the output plugin used for logical decoding (see [Section 51.6](#)).

TEMPORARY

Specify that this replication slot is a temporary one. Temporary slots are not saved to disk and are automatically dropped on error or when the session has finished.

RESERVE\_WAL

Specify that this physical replication slot reserves WAL immediately. Otherwise, WAL is only reserved upon connection from a streaming replication client.

EXPORT\_SNAPSHOT

NOEXPORT\_SNAPSHOT

USE\_SNAPSHOT

Decides what to do with the snapshot created during logical slot initialization. `EXPORT_SNAPSHOT`, which is the default, will export the snapshot for use in other sessions. This option can't be used inside a transaction. `USE_SNAPSHOT` will use the snapshot for the current transaction executing the command. This option must be used in a transaction, and `CREATE_REPLICATION_SLOT` must be the first command run in that transaction. Finally, `NOEXPORT_SNAPSHOT` will just use the snapshot for logical decoding as normal but won't do anything else with it.

In response to this command, the server will send a one-row result set containing the following fields:

*slot\_name* (text)

The name of the newly-created replication slot.

*consistent\_point* (text)

The WAL location at which the slot became consistent. This is the earliest location from which streaming can start on this replication slot.

*snapshot\_name* (text)

The identifier of the snapshot exported by the command. The snapshot is valid until a new command is executed on this connection or the replication connection is closed. Null if the created slot is physical.

*output\_plugin* (text)

The name of the output plugin used by the newly-created replication slot. Null if the created slot is physical.

`START_REPLICATION [ SLOT slot_name ] [ PHYSICAL ] XXX/XXX [ TIMELINE tli ]`

Instructs server to start streaming WAL, starting at WAL location `XXX/XXX`. If `TIMELINE` option is specified, streaming starts on timeline `tli`; otherwise, the server's current timeline is selected. The server can reply with an error, for example if the requested section of WAL has already been recycled. On success, the server responds with a `CopyBothResponse` message, and then starts to stream WAL to the frontend.

If a slot's name is provided via `slot_name`, it will be updated as replication progresses so that the server knows which WAL segments, and if `hot_standby_feedback` is on which transactions, are still needed by the standby.

If the client requests a timeline that's not the latest but is part of the history of the server, the server will stream all the WAL on that timeline starting from the requested start point up to the point where the server switched to another timeline. If the client requests streaming at exactly the end of an old timeline, the server skips COPY mode entirely.

After streaming all the WAL on a timeline that is not the latest one, the server will end streaming by exiting the COPY mode. When the client acknowledges this by also exiting COPY mode, the server sends a result set with one row and two columns, indicating the next timeline in this server's history. The first column is the next timeline's ID (type `int8`), and the second column is the WAL location where the switch happened (type `text`). Usually, the switch position is the end of the WAL that was streamed, but there are corner cases where the server can send some WAL from the old timeline that it has not itself replayed before promoting. Finally, the server sends two `CommandComplete` messages (one that ends the `CopyData` and the other ends the `START_REPLICATION` itself), and is ready to accept a new command.

WAL data is sent as a series of `CopyData` messages. (This allows other information to be intermixed; in particular the server can send an `ErrorResponse` message if it encounters a failure after beginning to stream.) The payload of each `CopyData` message from server to the client contains a message of one of the following formats:

**XLogData (B)**

Byte1('w')

Identifies the message as WAL data.

Int64

The starting point of the WAL data in this message.

Int64

The current end of WAL on the server.

Int64

The server's system clock at the time of transmission, as microseconds since midnight on 2000-01-01.

Byte<sub>n</sub>

A section of the WAL data stream.

A single WAL record is never split across two `XLogData` messages. When a WAL record crosses a WAL page boundary, and is therefore already split using continuation records, it can be split at the page boundary. In other words, the first main WAL record and its continuation records can be sent in different `XLogData` messages.

**Primary keepalive message (B)**

Byte1('k')

Identifies the message as a sender keepalive.

Int64

The current end of WAL on the server.

Int64

The server's system clock at the time of transmission, as microseconds since midnight on 2000-01-01.

Byte1

1 means that the client should reply to this message as soon as possible, to avoid a timeout disconnect. 0 otherwise.

The receiving process can send replies back to the sender at any time, using one of the following message formats (also in the payload of a `CopyData` message):

## Standby status update (F)

Byte1('r')

Identifies the message as a receiver status update.

Int64

The location of the last WAL byte + 1 received and written to disk in the standby.

Int64

The location of the last WAL byte + 1 flushed to disk in the standby.

Int64

The location of the last WAL byte + 1 applied in the standby.

Int64

The client's system clock at the time of transmission, as microseconds since midnight on 2000-01-01.

Byte1

If 1, the client requests the server to reply to this message immediately. This can be used to ping the server, to test if the connection is still healthy.

## Hot Standby feedback message (F)

Byte1('h')

Identifies the message as a Hot Standby feedback message.

Int64

The client's system clock at the time of transmission, as microseconds since midnight on 2000-01-01.

Int32

The standby's current global xmin, excluding the catalog\_xmin from any replication slots. If both this value and the following catalog\_xmin are 0 this is treated as a notification that Hot Standby feedback will no longer be sent on this connection. Later non-zero messages may reinitiate the feedback mechanism.

Int32

The epoch of the global xmin xid on the standby.

Int32

The lowest catalog\_xmin of any replication slots on the standby. Set to 0 if no catalog\_xmin exists on the standby or if hot standby feedback is being disabled.

Int32

The epoch of the catalog\_xmin xid on the standby.

`START_REPLICATION SLOT slot_name LOGICAL xxx/xxx [ ( option_name [ option_value ] [, ...] ) ]`

Instructs server to start streaming WAL for logical replication, starting at WAL location *xxx/xxx*. The server can reply with an error, for example if the requested section of WAL has already been recycled. On success, server responds with a CopyBothResponse message, and then starts to stream WAL to the frontend.

The messages inside the CopyBothResponse messages are of the same format documented for `START_REPLICATION ... PHYSICAL`, including two CommandComplete messages.

The output plugin associated with the selected slot is used to process the output for streaming.

*SLOT slot\_name*

The name of the slot to stream changes from. This parameter is required, and must correspond to an existing logical replication slot created with `CREATE_REPLICATION_SLOT` in LOGICAL mode.

*XXX/XXX*

The WAL location to begin streaming at.

*option\_name*

The name of an option passed to the slot's logical decoding output plugin. See [Section 55.5](#) for options that are accepted by the standard (`pgoutput`) plugin.

*option\_value*

Optional value, in the form of a string constant, associated with the specified option.

`DROP_REPLICATION_SLOT slot_name [ WAIT ]`

Drops a replication slot, freeing any reserved server-side resources.

*slot\_name*

The name of the slot to drop.

`WAIT`

This option causes the command to wait if the slot is active until it becomes inactive, instead of the default behavior of raising an error.

`BASE_BACKUP [ LABEL 'label' ] [ PROGRESS ] [ FAST ] [ WAL ] [ NOWAIT ] [ MAX_RATE rate ] [ TABLESPACE_MAP ] [ NOVERIFY_CHECKSUMS ] [ MANIFEST manifest_option ] [ MANIFEST_CHECKSUMS checksum_algorithm ]`

Instructs the server to start streaming a base backup. The system will automatically be put in backup mode before the backup is started, and taken out of it when the backup is complete. The following options are accepted:

`LABEL 'label'`

Sets the label of the backup. If none is specified, a backup label of `base backup` will be used. The quoting rules for the label are the same as a standard SQL string with [standard\\_conforming\\_strings](#) turned on.

`PROGRESS`

Request information required to generate a progress report. This will send back an approximate size in the header of each tablespace, which can be used to calculate how far along the stream is done. This is calculated by enumerating all the file sizes once before the transfer is even started, and might as such have a negative impact on the performance. In particular, it might take longer before the first data is streamed. Since the database files can change during the backup, the size is only approximate and might both grow and shrink between the time of approximation and the sending of the actual files.

`FAST`

Request a fast checkpoint.

`WAL`

Include the necessary WAL segments in the backup. This will include all the files between start and stop backup in the `pg_wal` directory of the base directory tar file.

**NOWAIT**

By default, the backup will wait until the last required WAL segment has been archived, or emit a warning if log archiving is not enabled. Specifying **NOWAIT** disables both the waiting and the warning, leaving the client responsible for ensuring the required log is available.

**MAX\_RATE** *rate*

Limit (throttle) the maximum amount of data transferred from server to client per unit of time. The expected unit is kilobytes per second. If this option is specified, the value must either be equal to zero or it must fall within the range from 32 kB through 1 GB (inclusive). If zero is passed or the option is not specified, no restriction is imposed on the transfer.

**TABLESPACE\_MAP**

Include information about symbolic links present in the directory `pg_tblspc` in a file named `tablespace_map`. The tablespace map file includes each symbolic link name as it exists in the directory `pg_tblspc/` and the full path of that symbolic link.

**NOVERIFY\_CHECKSUMS**

By default, checksums are verified during a base backup if they are enabled. Specifying **NOVERIFY\_CHECKSUMS** disables this verification.

**MANIFEST** *manifest\_option*

When this option is specified with a value of `yes` or `force-encode`, a backup manifest is created and sent along with the backup. The manifest is a list of every file present in the backup with the exception of any WAL files that may be included. It also stores the size, last modification time, and optionally a checksum for each file. A value of `force-encode` forces all filenames to be hex-encoded; otherwise, this type of encoding is performed only for files whose names are non-UTF8 octet sequences. `force-encode` is intended primarily for testing purposes, to be sure that clients which read the backup manifest can handle this case. For compatibility with previous releases, the default is `MANIFEST 'no'`.

**MANIFEST\_CHECKSUMS** *checksum\_algorithm*

Specifies the checksum algorithm that should be applied to each file included in the backup manifest. Currently, the available algorithms are `NONE`, `CRC32C`, `SHA224`, `SHA256`, `SHA384`, and `SHA512`. The default is `CRC32C`.

When the backup is started, the server will first send two ordinary result sets, followed by one or more `CopyOutResponse` results.

The first ordinary result set contains the starting position of the backup, in a single row with two columns. The first column contains the start position given in `XLogRecPtr` format, and the second column contains the corresponding timeline ID.

The second ordinary result set has one row for each tablespace. The fields in this row are:

`spcoid` (`oid`)

The OID of the tablespace, or null if it's the base directory.

`spcllocation` (`text`)

The full path of the tablespace directory, or null if it's the base directory.

`size` (`int8`)

The approximate size of the tablespace, in kilobytes (1024 bytes), if progress report has been requested; otherwise it's null.

After the second regular result set, one or more `CopyOutResponse` results will be sent, one for the main data directory and one for each additional tablespace other than `pg_default` and `pg_global`.

The data in the `CopyOutResponse` results will be a tar format (following the “ustar interchange format” specified in the POSIX 1003.1-2008 standard) dump of the tablespace contents, except that the two trailing blocks of zeroes specified in the standard are omitted. After the tar data is complete, and if a backup manifest was requested, another `CopyOutResponse` result is sent, containing the manifest data for the current base backup. In any case, a final ordinary result set will be sent, containing the WAL end position of the backup, in the same format as the start position.

The tar archive for the data directory and each tablespace will contain all files in the directories, regardless of whether they are Postgres Pro files or other files added to the same directory. The only excluded files are:

- `postmaster.pid`
- `postmaster.opts`
- `pg_internal.init` (found in multiple directories)
- Various temporary files and directories created during the operation of the Postgres Pro server, such as any file or directory beginning with `pgsql_tmp` and temporary relations.
- Unlogged relations, except for the init fork which is required to recreate the (empty) unlogged relation on recovery.
- `pg_wal`, including subdirectories. If the backup is run with WAL files included, a synthesized version of `pg_wal` will be included, but it will only contain the files necessary for the backup to work, not the rest of the contents.
- `pg_dynshmem`, `pg_notify`, `pg_replslot`, `pg_serial`, `pg_snapshots`, `pg_stat_tmp`, and `pg_subtrans` are copied as empty directories (even if they are symbolic links).
- Files other than regular files and directories, such as symbolic links (other than for the directories listed above) and special device files, are skipped. (Symbolic links in `pg_tblspc` are maintained.)

Owner, group, and file mode are set if the underlying file system on the server supports it.

## 55.5. Logical Streaming Replication Protocol

This section describes the logical replication protocol, which is the message flow started by the `START_REPLICATION SLOT slot_name LOGICAL` replication command.

The logical streaming replication protocol builds on the primitives of the physical streaming replication protocol.

PostgreSQL logical decoding supports output plugins. `pgoutput` is the standard one used for the built-in logical replication.

### 55.5.1. Logical Streaming Replication Parameters

Using the `START_REPLICATION` command, `pgoutput` accepts the following options:

`proto_version`

Protocol version. Currently versions 1 and 2 are supported. A valid version is required. The version 2 is supported only for server version 14 and above, and it allows streaming of large in-progress transactions.

`publication_names`

Comma separated list of publication names for which to subscribe (receive changes). The individual publication names are treated as standard objects names and can be quoted the same as needed. At least one publication name is required.

`binary`

Boolean option to use binary transfer mode. Binary mode is faster than the text mode but slightly less robust.

messages

Boolean option to enable sending the messages that are written by `pg_logical_emit_message`.

streaming

Boolean option to enable streaming of in-progress transactions. Minimum protocol version 2 is required to turn it on.

## 55.5.2. Logical Replication Protocol Messages

The individual protocol messages are discussed in the following subsections. Individual messages are described in [Section 55.9](#).

All top-level protocol messages begin with a message type byte. While represented in code as a character, this is a signed byte with no associated encoding.

Since the streaming replication protocol supplies a message length there is no need for top-level protocol messages to embed a length in their header.

## 55.5.3. Logical Replication Protocol Message Flow

With the exception of the `START_REPLICATION` command and the replay progress messages, all information flows only from the backend to the frontend.

The logical replication protocol sends individual transactions one by one. This means that all messages between a pair of Begin and Commit messages belong to the same transaction. It also sends changes of large in-progress transactions between a pair of Stream Start and Stream Stop messages. The last stream of such a transaction contains Stream Commit or Stream Abort message.

Every sent transaction contains zero or more DML messages (Insert, Update, Delete). In case of a cascaded setup it can also contain Origin messages. The origin message indicates that the transaction originated on different replication node. Since a replication node in the scope of logical replication protocol can be pretty much anything, the only identifier is the origin name. It's downstream's responsibility to handle this as needed (if needed). The Origin message is always sent before any DML messages in the transaction.

Every DML message contains a relation OID, identifying the publisher's relation that was acted on. Before the first DML message for a given relation OID, a Relation message will be sent, describing the schema of that relation. Subsequently, a new Relation message will be sent if the relation's definition has changed since the last Relation message was sent for it. (The protocol assumes that the client is capable of remembering this metadata for as many relations as needed.)

Relation messages identify column types by their OIDs. In the case of a built-in type, it is assumed that the client can look up that type OID locally, so no additional data is needed. For a non-built-in type OID, a Type message will be sent before the Relation message, to provide the type name associated with that OID. Thus, a client that needs to specifically identify the types of relation columns should cache the contents of Type messages, and first consult that cache to see if the type OID is defined there. If not, look up the type OID locally.

## 55.6. Message Data Types

This section describes the base data types used in messages.

`Int $n$ ( $i$ )`

An  $n$ -bit integer in network byte order (most significant byte first). If  $i$  is specified it is the exact value that will appear, otherwise the value is variable. Eg. `Int16`, `Int32(42)`.

`Int $n$ [ $k$ ]`

An array of  $k$   $n$ -bit integers, each in network byte order. The array length  $k$  is always determined by an earlier field in the message. Eg. `Int16[M]`.

**String(*s*)**

A null-terminated string (C-style string). There is no specific length limitation on strings. If *s* is specified it is the exact value that will appear, otherwise the value is variable. Eg. String, String("user").

**Note**

*There is no predefined limit on the length of a string that can be returned by the backend. Good coding strategy for a frontend is to use an expandable buffer so that anything that fits in memory can be accepted. If that's not feasible, read the full string and discard trailing characters that don't fit into your fixed-size buffer.*

**Byte<sub>*n*</sub>(*c*)**

Exactly *n* bytes. If the field width *n* is not a constant, it is always determinable from an earlier field in the message. If *c* is specified it is the exact value. Eg. Byte2, Byte1('\n').

## 55.7. Message Formats

This section describes the detailed format of each message. Each is marked to indicate that it can be sent by a frontend (F), a backend (B), or both (F & B). Notice that although each message includes a byte count at the beginning, the message format is defined so that the message end can be found without reference to the byte count. This aids validity checking. (The CopyData message is an exception, because it forms part of a data stream; the contents of any individual CopyData message cannot be interpretable on their own.)

**AuthenticationOk (B)**

Byte1('R')

Identifies the message as an authentication request.

Int32(8)

Length of message contents in bytes, including self.

Int32(0)

Specifies that the authentication was successful.

**AuthenticationKerberosV5 (B)**

Byte1('R')

Identifies the message as an authentication request.

Int32(8)

Length of message contents in bytes, including self.

Int32(2)

Specifies that Kerberos V5 authentication is required.

**AuthenticationCleartextPassword (B)**

Byte1('R')

Identifies the message as an authentication request.

Int32(8)

Length of message contents in bytes, including self.

Int32(3)

Specifies that a clear-text password is required.

**AuthenticationMD5Password (B)****Byte1('R')**

Identifies the message as an authentication request.

**Int32(12)**

Length of message contents in bytes, including self.

**Int32(5)**

Specifies that an MD5-encrypted password is required.

**Byte4**

The salt to use when encrypting the password.

**AuthenticationSCMCredential (B)****Byte1('R')**

Identifies the message as an authentication request.

**Int32(8)**

Length of message contents in bytes, including self.

**Int32(6)**

Specifies that an SCM credentials message is required.

**AuthenticationGSS (B)****Byte1('R')**

Identifies the message as an authentication request.

**Int32(8)**

Length of message contents in bytes, including self.

**Int32(7)**

Specifies that GSSAPI authentication is required.

**AuthenticationGSSContinue (B)****Byte1('R')**

Identifies the message as an authentication request.

**Int32**

Length of message contents in bytes, including self.

**Int32(8)**

Specifies that this message contains GSSAPI or SSPI data.

**Byte<sub>n</sub>**

GSSAPI or SSPI authentication data.

**AuthenticationSSPI (B)****Byte1('R')**

Identifies the message as an authentication request.

Int32(8)

Length of message contents in bytes, including self.

Int32(9)

Specifies that SSPI authentication is required.

AuthenticationSASL (B)

Byte1('R')

Identifies the message as an authentication request.

Int32

Length of message contents in bytes, including self.

Int32(10)

Specifies that SASL authentication is required.

The message body is a list of SASL authentication mechanisms, in the server's order of preference. A zero byte is required as terminator after the last authentication mechanism name. For each mechanism, there is the following:

String

Name of a SASL authentication mechanism.

AuthenticationSASLContinue (B)

Byte1('R')

Identifies the message as an authentication request.

Int32

Length of message contents in bytes, including self.

Int32(11)

Specifies that this message contains a SASL challenge.

Byte<sub>n</sub>

SASL data, specific to the SASL mechanism being used.

AuthenticationSASLFinal (B)

Byte1('R')

Identifies the message as an authentication request.

Int32

Length of message contents in bytes, including self.

Int32(12)

Specifies that SASL authentication has completed.

Byte<sub>n</sub>

SASL outcome "additional data", specific to the SASL mechanism being used.

BackendKeyData (B)

Byte1('K')

Identifies the message as cancellation key data. The frontend must save these values if it wishes to be able to issue CancelRequest messages later.

Int32(12)

Length of message contents in bytes, including self.

Int32

The process ID of this backend.

Int32

The secret key of this backend.

Bind (F)

Byte1('B')

Identifies the message as a Bind command.

Int32

Length of message contents in bytes, including self.

String

The name of the destination portal (an empty string selects the unnamed portal).

String

The name of the source prepared statement (an empty string selects the unnamed prepared statement).

Int16

The number of parameter format codes that follow (denoted *c* below). This can be zero to indicate that there are no parameters or that the parameters all use the default format (text); or one, in which case the specified format code is applied to all parameters; or it can equal the actual number of parameters.

Int16[*c*]

The parameter format codes. Each must presently be zero (text) or one (binary).

Int16

The number of parameter values that follow (possibly zero). This must match the number of parameters needed by the query.

Next, the following pair of fields appear for each parameter:

Int32

The length of the parameter value, in bytes (this count does not include itself). Can be zero. As a special case, -1 indicates a NULL parameter value. No value bytes follow in the NULL case.

Byte<sub>*n*</sub>

The value of the parameter, in the format indicated by the associated format code. *n* is the above length.

After the last parameter, the following fields appear:

Int16

The number of result-column format codes that follow (denoted *R* below). This can be zero to indicate that there are no result columns or that the result columns should all use the default format (text); or one, in which case the specified format code is applied to all result columns (if any); or it can equal the actual number of result columns of the query.

Int16[R]

The result-column format codes. Each must presently be zero (text) or one (binary).

BindComplete (B)

Byte1('2')

Identifies the message as a Bind-complete indicator.

Int32(4)

Length of message contents in bytes, including self.

CancelRequest (F)

Int32(16)

Length of message contents in bytes, including self.

Int32(80877102)

The cancel request code. The value is chosen to contain 1234 in the most significant 16 bits, and 5678 in the least significant 16 bits. (To avoid confusion, this code must not be the same as any protocol version number.)

Int32

The process ID of the target backend.

Int32

The secret key for the target backend.

Close (F)

Byte1('C')

Identifies the message as a Close command.

Int32

Length of message contents in bytes, including self.

Byte1

'S' to close a prepared statement; or 'P' to close a portal.

String

The name of the prepared statement or portal to close (an empty string selects the unnamed prepared statement or portal).

CloseComplete (B)

Byte1('3')

Identifies the message as a Close-complete indicator.

Int32(4)

Length of message contents in bytes, including self.

CommandComplete (B)

Byte1('C')

Identifies the message as a command-completed response.

Int32

Length of message contents in bytes, including self.

String

The command tag. This is usually a single word that identifies which SQL command was completed.

For an `INSERT` command, the tag is `INSERT oid rows`, where *rows* is the number of rows inserted. *oid* used to be the object ID of the inserted row if *rows* was 1 and the target table had OIDs, but OIDs system columns are not supported anymore; therefore *oid* is always 0.

For a `DELETE` command, the tag is `DELETE rows` where *rows* is the number of rows deleted.

For an `UPDATE` command, the tag is `UPDATE rows` where *rows* is the number of rows updated.

For a `SELECT` or `CREATE TABLE AS` command, the tag is `SELECT rows` where *rows* is the number of rows retrieved.

For a `MOVE` command, the tag is `MOVE rows` where *rows* is the number of rows the cursor's position has been changed by.

For a `FETCH` command, the tag is `FETCH rows` where *rows* is the number of rows that have been retrieved from the cursor.

For a `COPY` command, the tag is `COPY rows` where *rows* is the number of rows copied. (Note: the row count appears only in PostgreSQL 8.2 and later.)

CopyData (F & B)

Byte1('d')

Identifies the message as `COPY` data.

Int32

Length of message contents in bytes, including self.

Byten

Data that forms part of a `COPY` data stream. Messages sent from the backend will always correspond to single data rows, but messages sent by frontends might divide the data stream arbitrarily.

CopyDone (F & B)

Byte1('c')

Identifies the message as a `COPY`-complete indicator.

Int32(4)

Length of message contents in bytes, including self.

CopyFail (F)

Byte1('f')

Identifies the message as a `COPY`-failure indicator.

Int32

Length of message contents in bytes, including self.

String

An error message to report as the cause of failure.

**CopyInResponse (B)****Byte1('G')**

Identifies the message as a Start Copy In response. The frontend must now send copy-in data (if not prepared to do so, send a CopyFail message).

**Int32**

Length of message contents in bytes, including self.

**Int8**

0 indicates the overall `COPY` format is textual (rows separated by newlines, columns separated by separator characters, etc). 1 indicates the overall copy format is binary (similar to DataRow format). See [COPY](#) for more information.

**Int16**

The number of columns in the data to be copied (denoted  $N$  below).

**Int16[ $N$ ]**

The format codes to be used for each column. Each must presently be zero (text) or one (binary). All must be zero if the overall copy format is textual.

**CopyOutResponse (B)****Byte1('H')**

Identifies the message as a Start Copy Out response. This message will be followed by copy-out data.

**Int32**

Length of message contents in bytes, including self.

**Int8**

0 indicates the overall `COPY` format is textual (rows separated by newlines, columns separated by separator characters, etc). 1 indicates the overall copy format is binary (similar to DataRow format). See [COPY](#) for more information.

**Int16**

The number of columns in the data to be copied (denoted  $N$  below).

**Int16[ $N$ ]**

The format codes to be used for each column. Each must presently be zero (text) or one (binary). All must be zero if the overall copy format is textual.

**CopyBothResponse (B)****Byte1('W')**

Identifies the message as a Start Copy Both response. This message is used only for Streaming Replication.

**Int32**

Length of message contents in bytes, including self.

**Int8**

0 indicates the overall `COPY` format is textual (rows separated by newlines, columns separated by separator characters, etc). 1 indicates the overall copy format is binary (similar to DataRow format). See [COPY](#) for more information.

Int16

The number of columns in the data to be copied (denoted  $N$  below).

Int16[ $N$ ]

The format codes to be used for each column. Each must presently be zero (text) or one (binary). All must be zero if the overall copy format is textual.

DataRow (B)

Byte1('D')

Identifies the message as a data row.

Int32

Length of message contents in bytes, including self.

Int16

The number of column values that follow (possibly zero).

Next, the following pair of fields appear for each column:

Int32

The length of the column value, in bytes (this count does not include itself). Can be zero. As a special case, -1 indicates a NULL column value. No value bytes follow in the NULL case.

Byte $n$

The value of the column, in the format indicated by the associated format code.  $n$  is the above length.

Describe (F)

Byte1('D')

Identifies the message as a Describe command.

Int32

Length of message contents in bytes, including self.

Byte1

'S' to describe a prepared statement; or 'P' to describe a portal.

String

The name of the prepared statement or portal to describe (an empty string selects the unnamed prepared statement or portal).

EmptyQueryResponse (B)

Byte1('I')

Identifies the message as a response to an empty query string. (This substitutes for Command-Complete.)

Int32(4)

Length of message contents in bytes, including self.

ErrorResponse (B)

Byte1('E')

Identifies the message as an error.

**Int32**

Length of message contents in bytes, including self.

The message body consists of one or more identified fields, followed by a zero byte as a terminator. Fields can appear in any order. For each field there is the following:

**Byte1**

A code identifying the field type; if zero, this is the message terminator and no string follows. The presently defined field types are listed in [Section 55.8](#). Since more field types might be added in future, frontends should silently ignore fields of unrecognized type.

**String**

The field value.

**Execute (F)****Byte1('E')**

Identifies the message as an Execute command.

**Int32**

Length of message contents in bytes, including self.

**String**

The name of the portal to execute (an empty string selects the unnamed portal).

**Int32**

Maximum number of rows to return, if portal contains a query that returns rows (ignored otherwise). Zero denotes “no limit”.

**Flush (F)****Byte1('H')**

Identifies the message as a Flush command.

**Int32(4)**

Length of message contents in bytes, including self.

**FunctionCall (F)****Byte1('F')**

Identifies the message as a function call.

**Int32**

Length of message contents in bytes, including self.

**Int32**

Specifies the object ID of the function to call.

**Int16**

The number of argument format codes that follow (denoted *c* below). This can be zero to indicate that there are no arguments or that the arguments all use the default format (text); or one, in which case the specified format code is applied to all arguments; or it can equal the actual number of arguments.

**Int16[*c*]**

The argument format codes. Each must presently be zero (text) or one (binary).

Int16

Specifies the number of arguments being supplied to the function.

Next, the following pair of fields appear for each argument:

Int32

The length of the argument value, in bytes (this count does not include itself). Can be zero. As a special case, -1 indicates a NULL argument value. No value bytes follow in the NULL case.

Byte $n$

The value of the argument, in the format indicated by the associated format code.  $n$  is the above length.

After the last argument, the following field appears:

Int16

The format code for the function result. Must presently be zero (text) or one (binary).

FunctionCallResponse (B)

Byte1('V')

Identifies the message as a function call result.

Int32

Length of message contents in bytes, including self.

Int32

The length of the function result value, in bytes (this count does not include itself). Can be zero. As a special case, -1 indicates a NULL function result. No value bytes follow in the NULL case.

Byte $n$

The value of the function result, in the format indicated by the associated format code.  $n$  is the above length.

GSSENCRequest (F)

Int32(8)

Length of message contents in bytes, including self.

Int32(80877104)

The GSSAPI Encryption request code. The value is chosen to contain 1234 in the most significant 16 bits, and 5680 in the least significant 16 bits. (To avoid confusion, this code must not be the same as any protocol version number.)

GSSResponse (F)

Byte1('p')

Identifies the message as a GSSAPI or SSPI response. Note that this is also used for SASL and password response messages. The exact message type can be deduced from the context.

Int32

Length of message contents in bytes, including self.

Byte $n$

GSSAPI/SSPI specific message data.

**NegotiateProtocolVersion (B)**

Byte1('v')

Identifies the message as a protocol version negotiation message.

Int32

Length of message contents in bytes, including self.

Int32

Newest minor protocol version supported by the server for the major protocol version requested by the client.

Int32

Number of protocol options not recognized by the server.

Then, for protocol option not recognized by the server, there is the following:

String

The option name.

**NoData (B)**

Byte1('n')

Identifies the message as a no-data indicator.

Int32(4)

Length of message contents in bytes, including self.

**NoticeResponse (B)**

Byte1('N')

Identifies the message as a notice.

Int32

Length of message contents in bytes, including self.

The message body consists of one or more identified fields, followed by a zero byte as a terminator. Fields can appear in any order. For each field there is the following:

Byte1

A code identifying the field type; if zero, this is the message terminator and no string follows. The presently defined field types are listed in [Section 55.8](#). Since more field types might be added in future, frontends should silently ignore fields of unrecognized type.

String

The field value.

**NotificationResponse (B)**

Byte1('A')

Identifies the message as a notification response.

Int32

Length of message contents in bytes, including self.

Int32

The process ID of the notifying backend process.

String

The name of the channel that the notify has been raised on.

String

The “payload” string passed from the notifying process.

ParameterDescription (B)

Byte1('t')

Identifies the message as a parameter description.

Int32

Length of message contents in bytes, including self.

Int16

The number of parameters used by the statement (can be zero).

Then, for each parameter, there is the following:

Int32

Specifies the object ID of the parameter data type.

ParameterStatus (B)

Byte1('S')

Identifies the message as a run-time parameter status report.

Int32

Length of message contents in bytes, including self.

String

The name of the run-time parameter being reported.

String

The current value of the parameter.

Parse (F)

Byte1('P')

Identifies the message as a Parse command.

Int32

Length of message contents in bytes, including self.

String

The name of the destination prepared statement (an empty string selects the unnamed prepared statement).

String

The query string to be parsed.

Int16

The number of parameter data types specified (can be zero). Note that this is not an indication of the number of parameters that might appear in the query string, only the number that the frontend wants to prespecify types for.

Then, for each parameter, there is the following:

Int32

Specifies the object ID of the parameter data type. Placing a zero here is equivalent to leaving the type unspecified.

ParseComplete (B)

Byte1('1')

Identifies the message as a Parse-complete indicator.

Int32(4)

Length of message contents in bytes, including self.

PasswordMessage (F)

Byte1('p')

Identifies the message as a password response. Note that this is also used for GSSAPI, SSPI and SASL response messages. The exact message type can be deduced from the context.

Int32

Length of message contents in bytes, including self.

String

The password (encrypted, if requested).

PortalSuspended (B)

Byte1('s')

Identifies the message as a portal-suspended indicator. Note this only appears if an Execute message's row-count limit was reached.

Int32(4)

Length of message contents in bytes, including self.

Query (F)

Byte1('Q')

Identifies the message as a simple query.

Int32

Length of message contents in bytes, including self.

String

The query string itself.

ReadyForQuery (B)

Byte1('Z')

Identifies the message type. ReadyForQuery is sent whenever the backend is ready for a new query cycle.

Int32(5)

Length of message contents in bytes, including self.

Byte1

Current backend transaction status indicator. Possible values are 'I' if idle (not in a transaction block); 'T' if in a transaction block; or 'E' if in a failed transaction block (queries will be rejected until block is ended).

## RowDescription (B)

Byte1('T')

Identifies the message as a row description.

Int32

Length of message contents in bytes, including self.

Int16

Specifies the number of fields in a row (can be zero).

Then, for each field, there is the following:

String

The field name.

Int32

If the field can be identified as a column of a specific table, the object ID of the table; otherwise zero.

Int16

If the field can be identified as a column of a specific table, the attribute number of the column; otherwise zero.

Int32

The object ID of the field's data type.

Int16

The data type size (see `pg_type.typelen`). Note that negative values denote variable-width types.

Int32

The type modifier (see `pg_attribute.atttypmod`). The meaning of the modifier is type-specific.

Int16

The format code being used for the field. Currently will be zero (text) or one (binary). In a Row-Description returned from the statement variant of Describe, the format code is not yet known and will always be zero.

## SASLInitialResponse (F)

Byte1('p')

Identifies the message as an initial SASL response. Note that this is also used for GSSAPI, SSPI and password response messages. The exact message type is deduced from the context.

Int32

Length of message contents in bytes, including self.

String

Name of the SASL authentication mechanism that the client selected.

Int32

Length of SASL mechanism specific "Initial Client Response" that follows, or -1 if there is no Initial Response.

Byte<sub>n</sub>

SASL mechanism specific "Initial Response".

**SASLResponse (F)****Byte1('p')**

Identifies the message as a SASL response. Note that this is also used for GSSAPI, SSPI and password response messages. The exact message type can be deduced from the context.

**Int32**

Length of message contents in bytes, including self.

**Byte<sub>n</sub>**

SASL mechanism specific message data.

**SSLRequest (F)****Int32(8)**

Length of message contents in bytes, including self.

**Int32(80877103)**

The SSL request code. The value is chosen to contain `1234` in the most significant 16 bits, and `5679` in the least significant 16 bits. (To avoid confusion, this code must not be the same as any protocol version number.)

**StartupMessage (F)****Int32**

Length of message contents in bytes, including self.

**Int32(196608)**

The protocol version number. The most significant 16 bits are the major version number (3 for the protocol described here). The least significant 16 bits are the minor version number (0 for the protocol described here).

The protocol version number is followed by one or more pairs of parameter name and value strings. A zero byte is required as a terminator after the last name/value pair. Parameters can appear in any order. `user` is required, others are optional. Each parameter is specified as:

**String**

The parameter name. Currently recognized names are:

`user`

The database user name to connect as. Required; there is no default.

`database`

The database to connect to. Defaults to the user name.

`options`

Command-line arguments for the backend. (This is deprecated in favor of setting individual run-time parameters.) Spaces within this string are considered to separate arguments, unless escaped with a backslash (`\`); write `\\` to represent a literal backslash.

`replication`

Used to connect in streaming replication mode, where a small set of replication commands can be issued instead of SQL statements. Value can be `true`, `false`, or `database`, and the default is `false`. See [Section 55.4](#) for details.

In addition to the above, other parameters may be listed. Parameter names beginning with `_pq_` are reserved for use as protocol extensions, while others are treated as run-time parameters to

be set at backend start time. Such settings will be applied during backend start (after parsing the command-line arguments if any) and will act as session defaults.

String

The parameter value.

Sync (F)

Byte1('S')

Identifies the message as a Sync command.

Int32(4)

Length of message contents in bytes, including self.

Terminate (F)

Byte1('X')

Identifies the message as a termination.

Int32(4)

Length of message contents in bytes, including self.

## 55.8. Error and Notice Message Fields

This section describes the fields that can appear in ErrorResponse and NoticeResponse messages. Each field type has a single-byte identification token. Note that any given field type should appear at most once per message.

S

Severity: the field contents are `ERROR`, `FATAL`, or `PANIC` (in an error message), or `WARNING`, `NOTICE`, `DEBUG`, `INFO`, or `LOG` (in a notice message), or a localized translation of one of these. Always present.

V

Severity: the field contents are `ERROR`, `FATAL`, or `PANIC` (in an error message), or `WARNING`, `NOTICE`, `DEBUG`, `INFO`, or `LOG` (in a notice message). This is identical to the S field except that the contents are never localized. This is present only in messages generated by Postgres Pro versions 9.6 and later.

C

Code: the SQLSTATE code for the error (see [Appendix A](#)). Not localizable. Always present.

M

Message: the primary human-readable error message. This should be accurate but terse (typically one line). Always present.

D

Detail: an optional secondary error message carrying more detail about the problem. Might run to multiple lines.

H

Hint: an optional suggestion what to do about the problem. This is intended to differ from Detail in that it offers advice (potentially inappropriate) rather than hard facts. Might run to multiple lines.

P

Position: the field value is a decimal ASCII integer, indicating an error cursor position as an index into the original query string. The first character has index 1, and positions are measured in characters not bytes.

P

Internal position: this is defined the same as the P field, but it is used when the cursor position refers to an internally generated command rather than the one submitted by the client. The q field will always appear when this field appears.

Q

Internal query: the text of a failed internally-generated command. This could be, for example, an SQL query issued by a PL/pgSQL function.

W

Where: an indication of the context in which the error occurred. Presently this includes a call stack traceback of active procedural language functions and internally-generated queries. The trace is one entry per line, most recent first.

S

Schema name: if the error was associated with a specific database object, the name of the schema containing that object, if any.

T

Table name: if the error was associated with a specific table, the name of the table. (Refer to the schema name field for the name of the table's schema.)

C

Column name: if the error was associated with a specific table column, the name of the column. (Refer to the schema and table name fields to identify the table.)

D

Data type name: if the error was associated with a specific data type, the name of the data type. (Refer to the schema name field for the name of the data type's schema.)

N

Constraint name: if the error was associated with a specific constraint, the name of the constraint. Refer to fields listed above for the associated table or domain. (For this purpose, indexes are treated as constraints, even if they weren't created with constraint syntax.)

F

File: the file name of the source-code location where the error was reported.

L

Line: the line number of the source-code location where the error was reported.

R

Routine: the name of the source-code routine reporting the error.

### Note

The fields for schema name, table name, column name, data type name, and constraint name are supplied only for a limited number of error types; see [Appendix A](#). Frontends should not assume that the presence of any of these fields guarantees the presence of another field. Core error sources observe the interrelationships noted above, but user-defined functions may use these fields in other ways. In the same vein, clients should not assume that these fields denote contemporary objects in the current database.

The client is responsible for formatting displayed information to meet its needs; in particular it should break long lines as needed. Newline characters appearing in the error message fields should be treated as paragraph breaks, not line breaks.

## 55.9. Logical Replication Message Formats

This section describes the detailed format of each logical replication message. These messages are returned either by the replication slot SQL interface or are sent by a walsender. In case of a walsender they are encapsulated inside the replication protocol WAL messages as described in [Section 55.4](#) and generally obey same message flow as physical replication.

Begin

Byte1('B')

Identifies the message as a begin message.

Int64

The final LSN of the transaction.

Int64

Commit timestamp of the transaction. The value is in number of microseconds since Postgres Pro epoch (2000-01-01).

Int64

Xid of the transaction.

Message

Byte1('M')

Identifies the message as a logical decoding message.

Int64

Xid of the transaction (only present for streamed transactions). This field is available since protocol version 2.

Int8

Flags; Either 0 for no flags or 1 if the logical decoding message is transactional.

Int64

The LSN of the logical decoding message.

String

The prefix of the logical decoding message.

Int32

Length of the content.

Byte<sub>n</sub>

The content of the logical decoding message.

Commit

Byte1('C')

Identifies the message as a commit message.

Int8

Flags; currently unused (must be 0).

Int64

The LSN of the commit.

Int64

The end LSN of the transaction.

Int64

Commit timestamp of the transaction. The value is in number of microseconds since Postgres Pro epoch (2000-01-01).

Origin

Byte1('O')

Identifies the message as an origin message.

Int64

The LSN of the commit on the origin server.

String

Name of the origin.

Note that there can be multiple Origin messages inside a single transaction.

Relation

Byte1('R')

Identifies the message as a relation message.

Int64

Xid of the transaction (only present for streamed transactions). This field is available since protocol version 2.

Int32

ID of the relation.

String

Namespace (empty string for `pg_catalog`).

String

Relation name.

Int8

Replica identity setting for the relation (same as `relreplident` in `pg_class`).

Int16

Number of columns.

Next, the following message part appears for each column (except generated columns):

Int8

Flags for the column. Currently can be either 0 for no flags or 1 which marks the column as part of the key.

String

Name of the column.

Int32

ID of the column's data type.

Int32

Type modifier of the column (`atttypmod`).

Type

Byte1('Y')

Identifies the message as a type message.

Int64

Xid of the transaction (only present for streamed transactions). This field is available since protocol version 2.

Int32

ID of the data type.

String

Namespace (empty string for `pg_catalog`).

String

Name of the data type.

Insert

Byte1('I')

Identifies the message as an insert message.

Int64

Xid of the transaction (only present for streamed transactions). This field is available since protocol version 2.

Int32

ID of the relation corresponding to the ID in the relation message.

Byte1('N')

Identifies the following `TupleData` message as a new tuple.

`TupleData`

`TupleData` message part representing the contents of new tuple.

Update

Byte1('U')

Identifies the message as an update message.

Int64

Xid of the transaction (only present for streamed transactions). This field is available since protocol version 2.

Int32

ID of the relation corresponding to the ID in the relation message.

Byte1('K')

Identifies the following TupleData submessage as a key. This field is optional and is only present if the update changed data in any of the column(s) that are part of the REPLICA IDENTITY index.

Byte1('O')

Identifies the following TupleData submessage as an old tuple. This field is optional and is only present if table in which the update happened has REPLICA IDENTITY set to FULL.

TupleData

TupleData message part representing the contents of the old tuple or primary key. Only present if the previous 'O' or 'K' part is present.

Byte1('N')

Identifies the following TupleData message as a new tuple.

TupleData

TupleData message part representing the contents of a new tuple.

The Update message may contain either a 'K' message part or an 'O' message part or neither of them, but never both of them.

Delete

Byte1('D')

Identifies the message as a delete message.

Int64

Xid of the transaction (only present for streamed transactions). This field is available since protocol version 2.

Int32

ID of the relation corresponding to the ID in the relation message.

Byte1('K')

Identifies the following TupleData submessage as a key. This field is present if the table in which the delete has happened uses an index as REPLICA IDENTITY.

Byte1('O')

Identifies the following TupleData message as an old tuple. This field is present if the table in which the delete happened has REPLICA IDENTITY set to FULL.

TupleData

TupleData message part representing the contents of the old tuple or primary key, depending on the previous field.

The Delete message may contain either a 'K' message part or an 'O' message part, but never both of them.

Truncate

Byte1('T')

Identifies the message as a truncate message.

Int64

Xid of the transaction (only present for streamed transactions). This field is available since protocol version 2.

Int32

Number of relations

Int8

Option bits for `TRUNCATE`: 1 for `CASCADE`, 2 for `RESTART IDENTITY`

Int32

ID of the relation corresponding to the ID in the relation message. This field is repeated for each relation.

The following messages (Stream Start, Stream Stop, Stream Commit, and Stream Abort) are available since protocol version 2.

#### Stream Start

Byte1('S')

Identifies the message as a stream start message.

Int64

Xid of the transaction.

Int8

A value of 1 indicates this is the first stream segment for this XID, 0 for any other stream segment.

#### Stream Stop

Byte1('E')

Identifies the message as a stream stop message.

#### Stream Commit

Byte1('c')

Identifies the message as a stream commit message.

Int64

Xid of the transaction.

Int8

Flags; currently unused (must be 0).

Int64

The LSN of the commit.

Int64

The end LSN of the transaction.

Int64

Commit timestamp of the transaction. The value is in number of microseconds since PostgreSQL epoch (2000-01-01).

#### Stream Abort

Byte1('A')

Identifies the message as a stream abort message.

Int64

Xid of the transaction.

Int64

Xid of the subtransaction (will be same as xid of the transaction for top-level transactions).

The following message parts are shared by the above messages.

TupleData

Int16

Number of columns.

Next, one of the following submessages appears for each column (except generated columns):

Byte1('n')

Identifies the data as NULL value.

Or

Byte1('u')

Identifies unchanged TOASTed value (the actual value is not sent).

Or

Byte1('t')

Identifies the data as text formatted value.

Or

Byte1('b')

Identifies the data as binary formatted value.

Int32

Length of the column value.

Byte<sub>*n*</sub>

The value of the column, either in binary or in text format. (As specified in the preceding format byte). *n* is the above length.

## 55.10. Summary of Changes since Protocol 2.0

This section provides a quick checklist of changes, for the benefit of developers trying to update existing client libraries to protocol 3.0.

The initial startup packet uses a flexible list-of-strings format instead of a fixed format. Notice that session default values for run-time parameters can now be specified directly in the startup packet. (Actually, you could do that before using the `options` field, but given the limited width of `options` and the lack of any way to quote whitespace in the values, it wasn't a very safe technique.)

All messages now have a length count immediately following the message type byte (except for startup packets, which have no type byte). Also note that `PasswordMessage` now has a type byte.

`ErrorResponse` and `NoticeResponse` ('E' and 'N') messages now contain multiple fields, from which the client code can assemble an error message of the desired level of verbosity. Note that individual fields will typically not end with a newline, whereas the single string sent in the older protocol always did.

The `ReadyForQuery` ('Z') message includes a transaction status indicator.

The distinction between `BinaryRow` and `DataRow` message types is gone; the single `DataRow` message type serves for returning data in all formats. Note that the layout of `DataRow` has changed to make it easier to parse. Also, the representation of binary values has changed: it is no longer directly tied to the server's internal representation.

There is a new “extended query” sub-protocol, which adds the frontend message types `Parse`, `Bind`, `Execute`, `Describe`, `Close`, `Flush`, and `Sync`, and the backend message types `ParseComplete`, `BindComplete`, `PortalSuspended`, `ParameterDescription`, `NoData`, and `CloseComplete`. Existing clients do not have to concern themselves with this sub-protocol, but making use of it might allow improvements in performance or functionality.

`COPY` data is now encapsulated into `CopyData` and `CopyDone` messages. There is a well-defined way to recover from errors during `COPY`. The special “\.” last line is not needed anymore, and is not sent during `COPY OUT`. (It is still recognized as a terminator during `COPY IN`, but its use is deprecated and will eventually be removed.) Binary `COPY` is supported. The `CopyInResponse` and `CopyOutResponse` messages include fields indicating the number of columns and the format of each column.

The layout of `FunctionCall` and `FunctionCallResponse` messages has changed. `FunctionCall` can now support passing `NULL` arguments to functions. It also can handle passing parameters and retrieving results in either text or binary format. There is no longer any reason to consider `FunctionCall` a potential security hole, since it does not offer direct access to internal server data representations.

The backend sends `ParameterStatus` ('S') messages during connection startup for all parameters it considers interesting to the client library. Subsequently, a `ParameterStatus` message is sent whenever the active value changes for any of these parameters.

The `RowDescription` ('T') message carries new table OID and column number fields for each column of the described row. It also shows the format code for each column.

The `CursorResponse` ('P') message is no longer generated by the backend.

The `NotificationResponse` ('A') message has an additional string field, which can carry a “payload” string passed from the `NOTIFY` event sender.

The `EmptyQueryResponse` ('I') message used to include an empty string parameter; this has been removed.

---

## Chapter 56. Writing a Procedural Language Handler

All calls to functions that are written in a language other than the current “version 1” interface for compiled languages (this includes functions in user-defined procedural languages and functions written in SQL) go through a *call handler* function for the specific language. It is the responsibility of the call handler to execute the function in a meaningful way, such as by interpreting the supplied source text. This chapter outlines how a new procedural language's call handler can be written.

The call handler for a procedural language is a “normal” function that must be written in a compiled language such as C, using the version-1 interface, and registered with Postgres Pro as taking no arguments and returning the type `language_handler`. This special pseudo-type identifies the function as a call handler and prevents it from being called directly in SQL commands. For more details on C language calling conventions and dynamic loading, see [Section 40.10](#).

The call handler is called in the same way as any other function: It receives a pointer to a `FunctionCallInfoBaseData` struct containing argument values and information about the called function, and it is expected to return a `Datum` result (and possibly set the `isnull` field of the `FunctionCallInfoBaseData` structure, if it wishes to return an SQL null result). The difference between a call handler and an ordinary callee function is that the `flinfo->fn_oid` field of the `FunctionCallInfoBaseData` structure will contain the OID of the actual function to be called, not of the call handler itself. The call handler must use this field to determine which function to execute. Also, the passed argument list has been set up according to the declaration of the target function, not of the call handler.

It's up to the call handler to fetch the entry of the function from the `pg_proc` system catalog and to analyze the argument and return types of the called function. The `AS` clause from the `CREATE FUNCTION` command for the function will be found in the `prosrc` column of the `pg_proc` row. This is commonly source text in the procedural language, but in theory it could be something else, such as a path name to a file, or anything else that tells the call handler what to do in detail.

Often, the same function is called many times per SQL statement. A call handler can avoid repeated lookups of information about the called function by using the `flinfo->fn_extra` field. This will initially be `NULL`, but can be set by the call handler to point at information about the called function. On subsequent calls, if `flinfo->fn_extra` is already non-`NULL` then it can be used and the information lookup step skipped. The call handler must make sure that `flinfo->fn_extra` is made to point at memory that will live at least until the end of the current query, since an `FmgrInfo` data structure could be kept that long. One way to do this is to allocate the extra data in the memory context specified by `flinfo->fn_mcxt`; such data will normally have the same lifespan as the `FmgrInfo` itself. But the handler could also choose to use a longer-lived memory context so that it can cache function definition information across queries.

When a procedural-language function is invoked as a trigger, no arguments are passed in the usual way, but the `FunctionCallInfoBaseData`'s `context` field points at a `TriggerData` structure, rather than being `NULL` as it is in a plain function call. A language handler should provide mechanisms for procedural-language functions to get at the trigger information.

Although providing a call handler is sufficient to create a minimal procedural language, there are two other functions that can optionally be provided to make the language more convenient to use. These are a *validator* and an *inline handler*. A validator can be provided to allow language-specific checking to be done during [CREATE FUNCTION](#). An inline handler can be provided to allow the language to support anonymous code blocks executed via the [DO](#) command.

If a validator is provided by a procedural language, it must be declared as a function taking a single parameter of type `oid`. The validator's result is ignored, so it is customarily declared to return `void`. The validator will be called at the end of a `CREATE FUNCTION` command that has created or updated a function written in the procedural language. The passed-in OID is the OID of the function's `pg_proc` row. The validator must fetch this row in the usual way, and do whatever checking is appropriate. First, call `CheckFunctionValidatorAccess()` to diagnose explicit calls to the validator that the user could not

achieve through `CREATE FUNCTION`. Typical checks then include verifying that the function's argument and result types are supported by the language, and that the function's body is syntactically correct in the language. If the validator finds the function to be okay, it should just return. If it finds an error, it should report that via the normal `ereport()` error reporting mechanism. Throwing an error will force a transaction rollback and thus prevent the incorrect function definition from being committed.

Validator functions should typically honor the `check_function_bodies` parameter: if it is turned off then any expensive or context-sensitive checking should be skipped. If the language provides for code execution at compilation time, the validator must suppress checks that would induce such execution. In particular, this parameter is turned off by `pg_dump` so that it can load procedural language functions without worrying about side effects or dependencies of the function bodies on other database objects. (Because of this requirement, the call handler should avoid assuming that the validator has fully checked the function. The point of having a validator is not to let the call handler omit checks, but to notify the user immediately if there are obvious errors in a `CREATE FUNCTION` command.) While the choice of exactly what to check is mostly left to the discretion of the validator function, note that the core `CREATE FUNCTION` code only executes `SET` clauses attached to a function when `check_function_bodies` is on. Therefore, checks whose results might be affected by GUC parameters definitely should be skipped when `check_function_bodies` is off, to avoid false failures when restoring a dump.

If an inline handler is provided by a procedural language, it must be declared as a function taking a single parameter of type `internal`. The inline handler's result is ignored, so it is customarily declared to return `void`. The inline handler will be called when a `DO` statement is executed specifying the procedural language. The parameter actually passed is a pointer to an `InlineCodeBlock` struct, which contains information about the `DO` statement's parameters, in particular the text of the anonymous code block to be executed. The inline handler should execute this code and return.

It's recommended that you wrap all these function declarations, as well as the `CREATE LANGUAGE` command itself, into an *extension* so that a simple `CREATE EXTENSION` command is sufficient to install the language. See [Section 40.17](#) for information about writing extensions.

The procedural languages included in the standard distribution are good references when trying to write your own language handler. The [CREATE LANGUAGE](#) reference page has some useful details.

---

# Chapter 57. Writing a Foreign Data Wrapper

All operations on a foreign table are handled through its foreign data wrapper, which consists of a set of functions that the core server calls. The foreign data wrapper is responsible for fetching data from the remote data source and returning it to the Postgres Pro executor. If updating foreign tables is to be supported, the wrapper must handle that, too. This chapter outlines how to write a new foreign data wrapper.

The foreign data wrappers included in the standard distribution are good references when trying to write your own. Look into the `contrib` subdirectory of the source tree. The [CREATE FOREIGN DATA WRAPPER](#) reference page also has some useful details.

## Note

The SQL standard specifies an interface for writing foreign data wrappers. However, Postgres Pro does not implement that API, because the effort to accommodate it into Postgres Pro would be large, and the standard API hasn't gained wide adoption anyway.

## 57.1. Foreign Data Wrapper Functions

The FDW author needs to implement a handler function, and optionally a validator function. Both functions must be written in a compiled language such as C, using the version-1 interface. For details on C language calling conventions and dynamic loading, see [Section 40.10](#).

The handler function simply returns a struct of function pointers to callback functions that will be called by the planner, executor, and various maintenance commands. Most of the effort in writing an FDW is in implementing these callback functions. The handler function must be registered with Postgres Pro as taking no arguments and returning the special pseudo-type `fdw_handler`. The callback functions are plain C functions and are not visible or callable at the SQL level. The callback functions are described in [Section 57.2](#).

The validator function is responsible for validating options given in `CREATE` and `ALTER` commands for its foreign data wrapper, as well as foreign servers, user mappings, and foreign tables using the wrapper. The validator function must be registered as taking two arguments, a text array containing the options to be validated, and an OID representing the type of object the options are associated with. The latter corresponds to the OID of the system catalog the object would be stored in, one of:

- `AttributeRelationId`
- `ForeignDataWrapperRelationId`
- `ForeignServerRelationId`
- `ForeignTableRelationId`
- `UserMappingRelationId`

If no validator function is supplied, options are not checked at object creation time or object alteration time.

## 57.2. Foreign Data Wrapper Callback Routines

The FDW handler function returns a palloc'd `FdwRoutine` struct containing pointers to the callback functions described below. The scan-related functions are required, the rest are optional.

The `FdwRoutine` struct type is declared in `src/include/foreign/fdwapi.h`, which see for additional details.

### 57.2.1. FDW Routines for Scanning Foreign Tables

```
void
GetForeignRelSize(PlannerInfo *root,
```

```
RelOptInfo *baserel,  
Oid foreigntableid);
```

Obtain relation size estimates for a foreign table. This is called at the beginning of planning for a query that scans a foreign table. `root` is the planner's global information about the query; `baserel` is the planner's information about this table; and `foreigntableid` is the `pg_class` OID of the foreign table. (`foreigntableid` could be obtained from the planner data structures, but it's passed explicitly to save effort.)

This function should update `baserel->rows` to be the expected number of rows returned by the table scan, after accounting for the filtering done by the restriction quals. The initial value of `baserel->rows` is just a constant default estimate, which should be replaced if at all possible. The function may also choose to update `baserel->width` if it can compute a better estimate of the average result row width. (The initial value is based on column data types and on column average-width values measured by the last `ANALYZE`.) Also, this function may update `baserel->tuples` if it can compute a better estimate of the foreign table's total row count. (The initial value is from `pg_class.reltuples` which represents the total row count seen by the last `ANALYZE`; it will be `-1` if no `ANALYZE` has been done on this foreign table.)

See [Section 57.4](#) for additional information.

```
void  
GetForeignPaths(PlannerInfo *root,  
                RelOptInfo *baserel,  
                Oid foreigntableid);
```

Create possible access paths for a scan on a foreign table. This is called during query planning. The parameters are the same as for `GetForeignRelSize`, which has already been called.

This function must generate at least one access path (`ForeignPath` node) for a scan on the foreign table and must call `add_path` to add each such path to `baserel->pathlist`. It's recommended to use `create_foreignscan_path` to build the `ForeignPath` nodes. The function can generate multiple access paths, e.g., a path which has valid `pathkeys` to represent a pre-sorted result. Each access path must contain cost estimates, and can contain any FDW-private information that is needed to identify the specific scan method intended.

See [Section 57.4](#) for additional information.

```
ForeignScan *  
GetForeignPlan(PlannerInfo *root,  
               RelOptInfo *baserel,  
               Oid foreigntableid,  
               ForeignPath *best_path,  
               List *tlist,  
               List *scan_clauses,  
               Plan *outer_plan);
```

Create a `ForeignScan` plan node from the selected foreign access path. This is called at the end of query planning. The parameters are as for `GetForeignRelSize`, plus the selected `ForeignPath` (previously produced by `GetForeignPaths`, `GetForeignJoinPaths`, or `GetForeignUpperPaths`), the target list to be emitted by the plan node, the restriction clauses to be enforced by the plan node, and the outer subplan of the `ForeignScan`, which is used for rechecks performed by `RecheckForeignScan`. (If the path is for a join rather than a base relation, `foreigntableid` is `InvalidOid`.)

This function must create and return a `ForeignScan` plan node; it's recommended to use `make_foreignscan` to build the `ForeignScan` node.

See [Section 57.4](#) for additional information.

```
void  
BeginForeignScan(ForeignScanState *node,  
                 int eflags);
```

Begin executing a foreign scan. This is called during executor startup. It should perform any initialization needed before the scan can start, but not start executing the actual scan (that should be done upon the first call to `IterateForeignScan`). The `ForeignScanState` node has already been created, but its `fdw_state` field is still `NULL`. Information about the table to scan is accessible through the `ForeignScanState` node (in particular, from the underlying `ForeignScan` plan node, which contains any FDW-private information provided by `GetForeignPlan`). `eflags` contains flag bits describing the executor's operating mode for this plan node.

Note that when `(eflags & EXEC_FLAG_EXPLAIN_ONLY)` is true, this function should not perform any externally-visible actions; it should only do the minimum required to make the node state valid for `ExplainForeignScan` and `EndForeignScan`.

```
TupleTableSlot *  
IterateForeignScan(ForeignScanState *node);
```

Fetch one row from the foreign source, returning it in a tuple table slot (the node's `ScanTupleSlot` should be used for this purpose). Return `NULL` if no more rows are available. The tuple table slot infrastructure allows either a physical or virtual tuple to be returned; in most cases the latter choice is preferable from a performance standpoint. Note that this is called in a short-lived memory context that will be reset between invocations. Create a memory context in `BeginForeignScan` if you need longer-lived storage, or use the `es_query_cxt` of the node's `EState`.

The rows returned must match the `fdw_scan_tlist` target list if one was supplied, otherwise they must match the row type of the foreign table being scanned. If you choose to optimize away fetching columns that are not needed, you should insert nulls in those column positions, or else generate a `fdw_scan_tlist` list with those columns omitted.

Note that Postgres Pro's executor doesn't care whether the rows returned violate any constraints that were defined on the foreign table — but the planner does care, and may optimize queries incorrectly if there are rows visible in the foreign table that do not satisfy a declared constraint. If a constraint is violated when the user has declared that the constraint should hold true, it may be appropriate to raise an error (just as you would need to do in the case of a data type mismatch).

```
void  
ReScanForeignScan(ForeignScanState *node);
```

Restart the scan from the beginning. Note that any parameters the scan depends on may have changed value, so the new scan does not necessarily return exactly the same rows.

```
void  
EndForeignScan(ForeignScanState *node);
```

End the scan and release resources. It is normally not important to release `palloc'd` memory, but for example open files and connections to remote servers should be cleaned up.

## 57.2.2. FDW Routines for Scanning Foreign Joins

If an FDW supports performing foreign joins remotely (rather than by fetching both tables' data and doing the join locally), it should provide this callback function:

```
void  
GetForeignJoinPaths(PlannerInfo *root,  
                   RelOptInfo *joinrel,  
                   RelOptInfo *outerrel,  
                   RelOptInfo *innerrel,  
                   JoinType jointype,  
                   JoinPathExtraData *extra);
```

Create possible access paths for a join of two (or more) foreign tables that all belong to the same foreign server. This optional function is called during query planning. As with `GetForeignPaths`, this function should generate `ForeignPath` path(s) for the supplied `joinrel` (use `create_foreign_join_path` to build

them), and call `add_path` to add these paths to the set of paths considered for the join. But unlike `GetForeignPaths`, it is not necessary that this function succeed in creating at least one path, since paths involving local joining are always possible.

Note that this function will be invoked repeatedly for the same join relation, with different combinations of inner and outer relations; it is the responsibility of the FDW to minimize duplicated work.

If a `ForeignPath` path is chosen for the join, it will represent the entire join process; paths generated for the component tables and subsidiary joins will not be used. Subsequent processing of the join path proceeds much as it does for a path scanning a single foreign table. One difference is that the `scanrelid` of the resulting `ForeignScan` plan node should be set to zero, since there is no single relation that it represents; instead, the `fs_relids` field of the `ForeignScan` node represents the set of relations that were joined. (The latter field is set up automatically by the core planner code, and need not be filled by the FDW.) Another difference is that, because the column list for a remote join cannot be found from the system catalogs, the FDW must fill `fdw_scan_tlist` with an appropriate list of `TargetEntry` nodes, representing the set of columns it will supply at run time in the tuples it returns.

See [Section 57.4](#) for additional information.

### 57.2.3. FDW Routines for Planning Post-Scan/Join Processing

If an FDW supports performing remote post-scan/join processing, such as remote aggregation, it should provide this callback function:

```
void
GetForeignUpperPaths(PlannerInfo *root,
                    UpperRelationKind stage,
                    RelOptInfo *input_rel,
                    RelOptInfo *output_rel,
                    void *extra);
```

Create possible access paths for *upper relation* processing, which is the planner's term for all post-scan/join query processing, such as aggregation, window functions, sorting, and table updates. This optional function is called during query planning. Currently, it is called only if all base relation(s) involved in the query belong to the same FDW. This function should generate `ForeignPath` path(s) for any post-scan/join processing that the FDW knows how to perform remotely (use `create_foreign_upper_path` to build them), and call `add_path` to add these paths to the indicated upper relation. As with `GetForeignJoinPaths`, it is not necessary that this function succeed in creating any paths, since paths involving local processing are always possible.

The `stage` parameter identifies which post-scan/join step is currently being considered. `output_rel` is the upper relation that should receive paths representing computation of this step, and `input_rel` is the relation representing the input to this step. The `extra` parameter provides additional details, currently, it is set only for `UPPERREL_PARTIAL_GROUP_AGG` or `UPPERREL_GROUP_AGG`, in which case it points to a `GroupPathExtraData` structure; or for `UPPERREL_FINAL`, in which case it points to a `FinalPathExtraData` structure. (Note that `ForeignPath` paths added to `output_rel` would typically not have any direct dependency on paths of the `input_rel`, since their processing is expected to be done externally. However, examining paths previously generated for the previous processing step can be useful to avoid redundant planning work.)

See [Section 57.4](#) for additional information.

### 57.2.4. FDW Routines for Updating Foreign Tables

If an FDW supports writable foreign tables, it should provide some or all of the following callback functions depending on the needs and capabilities of the FDW:

```
void
AddForeignUpdateTargets(PlannerInfo *root,
                      Index rtindex,
```

```
RangeTblEntry *target_rte,  
Relation target_relation);
```

UPDATE and DELETE operations are performed against rows previously fetched by the table-scanning functions. The FDW may need extra information, such as a row ID or the values of primary-key columns, to ensure that it can identify the exact row to update or delete. To support that, this function can add extra hidden, or “junk”, target columns to the list of columns that are to be retrieved from the foreign table during an UPDATE or DELETE.

To do that, construct a Var representing an extra value you need, and pass it to `add_row_identity_var`, along with a name for the junk column. (You can do this more than once if several columns are needed.) You must choose a distinct junk column name for each different Var you need, except that Vars that are identical except for the `varno` field can and should share a column name. The core system uses the junk column names `tableoid` for a table's `tableoid` column, `ctid` or `ctidN` for `ctid`, `wholerow` for a whole-row Var marked with `vartype = RECORD`, and `wholerowN` for a whole-row Var with `vartype` equal to the table's declared row type. Re-use these names when you can (the planner will combine duplicate requests for identical junk columns). If you need another kind of junk column besides these, it might be wise to choose a name prefixed with your extension name, to avoid conflicts against other FDWs.

If the `AddForeignUpdateTargets` pointer is set to `NULL`, no extra target expressions are added. (This will make it impossible to implement DELETE operations, though UPDATE may still be feasible if the FDW relies on an unchanging primary key to identify rows.)

```
List *  
PlanForeignModify(PlannerInfo *root,  
                  ModifyTable *plan,  
                  Index resultRelation,  
                  int subplan_index);
```

Perform any additional planning actions needed for an insert, update, or delete on a foreign table. This function generates the FDW-private information that will be attached to the `ModifyTable` plan node that performs the update action. This private information must have the form of a `List`, and will be delivered to `BeginForeignModify` during the execution stage.

`root` is the planner's global information about the query. `plan` is the `ModifyTable` plan node, which is complete except for the `fdwPrivLists` field. `resultRelation` identifies the target foreign table by its range table index. `subplan_index` identifies which target of the `ModifyTable` plan node this is, counting from zero; use this if you want to index into per-target-relation substructures of the `plan` node.

See [Section 57.4](#) for additional information.

If the `PlanForeignModify` pointer is set to `NULL`, no additional plan-time actions are taken, and the `fdw_private` list delivered to `BeginForeignModify` will be `NIL`.

```
void  
BeginForeignModify(ModifyTableState *mtstate,  
                  ResultRelInfo *rinfo,  
                  List *fdw_private,  
                  int subplan_index,  
                  int eflags);
```

Begin executing a foreign table modification operation. This routine is called during executor startup. It should perform any initialization needed prior to the actual table modifications. Subsequently, `ExecForeignInsert`/`ExecForeignBatchInsert`, `ExecForeignUpdate` or `ExecForeignDelete` will be called for tuple(s) to be inserted, updated, or deleted.

`mtstate` is the overall state of the `ModifyTable` plan node being executed; global data about the plan and execution state is available via this structure. `rinfo` is the `ResultRelInfo` struct describing the target foreign table. (The `ri_FdwState` field of `ResultRelInfo` is available for the FDW to store any private state it needs for this operation.) `fdw_private` contains the private data generated by `PlanForeignModify`, if

any. `subplan_index` identifies which target of the `ModifyTable` plan node this is. `eflags` contains flag bits describing the executor's operating mode for this plan node.

Note that when `(eflags & EXEC_FLAG_EXPLAIN_ONLY)` is true, this function should not perform any externally-visible actions; it should only do the minimum required to make the node state valid for `ExplainForeignModify` and `EndForeignModify`.

If the `BeginForeignModify` pointer is set to `NULL`, no action is taken during executor startup.

```
TupleTableSlot *
ExecForeignInsert (EState *estate,
                  ResultRelInfo *rinfo,
                  TupleTableSlot *slot,
                  TupleTableSlot *planSlot);
```

Insert one tuple into the foreign table. `estate` is global execution state for the query. `rinfo` is the `ResultRelInfo` struct describing the target foreign table. `slot` contains the tuple to be inserted; it will match the row-type definition of the foreign table. `planSlot` contains the tuple that was generated by the `ModifyTable` plan node's subplan; it differs from `slot` in possibly containing additional “junk” columns. (The `planSlot` is typically of little interest for `INSERT` cases, but is provided for completeness.)

The return value is either a slot containing the data that was actually inserted (this might differ from the data supplied, for example as a result of trigger actions), or `NULL` if no row was actually inserted (again, typically as a result of triggers). The passed-in `slot` can be re-used for this purpose.

The data in the returned slot is used only if the `INSERT` statement has a `RETURNING` clause or involves a view `WITH CHECK OPTION`; or if the foreign table has an `AFTER ROW` trigger. Triggers require all columns, but the FDW could choose to optimize away returning some or all columns depending on the contents of the `RETURNING` clause or `WITH CHECK OPTION` constraints. Regardless, some slot must be returned to indicate success, or the query's reported row count will be wrong.

If the `ExecForeignInsert` pointer is set to `NULL`, attempts to insert into the foreign table will fail with an error message.

Note that this function is also called when inserting routed tuples into a foreign-table partition or executing `COPY FROM` on a foreign table, in which case it is called in a different way than it is in the `INSERT` case. See the callback functions described below that allow the FDW to support that.

```
TupleTableSlot **
ExecForeignBatchInsert (EState *estate,
                      ResultRelInfo *rinfo,
                      TupleTableSlot **slots,
                      TupleTableSlot **planSlots,
                      int *numSlots);
```

Insert multiple tuples in bulk into the foreign table. The parameters are the same for `ExecForeignInsert` except `slots` and `planSlots` contain multiple tuples and `*numSlots` specifies the number of tuples in those arrays.

The return value is an array of slots containing the data that was actually inserted (this might differ from the data supplied, for example as a result of trigger actions.) The passed-in `slots` can be re-used for this purpose. The number of successfully inserted tuples is returned in `*numSlots`.

The data in the returned slot is used only if the `INSERT` statement involves a view `WITH CHECK OPTION`; or if the foreign table has an `AFTER ROW` trigger. Triggers require all columns, but the FDW could choose to optimize away returning some or all columns depending on the contents of the `WITH CHECK OPTION` constraints.

If the `ExecForeignBatchInsert` or `GetForeignModifyBatchSize` pointer is set to `NULL`, attempts to insert into the foreign table will use `ExecForeignInsert`. This function is not used if the `INSERT` has the `RETURNING` clause.

Note that this function is also called when inserting routed tuples into a foreign-table partition. See the callback functions described below that allow the FDW to support that.

```
int
GetForeignModifyBatchSize(ResultRelInfo *rinfo);
```

Report the maximum number of tuples that a single `ExecForeignBatchInsert` call can handle for the specified foreign table. The executor passes at most the given number of tuples to `ExecForeignBatchInsert`. `rinfo` is the `ResultRelInfo` struct describing the target foreign table. The FDW is expected to provide a foreign server and/or foreign table option for the user to set this value, or some hard-coded value.

If the `ExecForeignBatchInsert` or `GetForeignModifyBatchSize` pointer is set to `NULL`, attempts to insert into the foreign table will use `ExecForeignInsert`.

```
TupleTableSlot *
ExecForeignUpdate(EState *estate,
                  ResultRelInfo *rinfo,
                  TupleTableSlot *slot,
                  TupleTableSlot *planSlot);
```

Update one tuple in the foreign table. `estate` is global execution state for the query. `rinfo` is the `ResultRelInfo` struct describing the target foreign table. `slot` contains the new data for the tuple; it will match the row-type definition of the foreign table. `planSlot` contains the tuple that was generated by the `ModifyTable` plan node's subplan. Unlike `slot`, this tuple contains only the new values for columns changed by the query, so do not rely on attribute numbers of the foreign table to index into `planSlot`. Also, `planSlot` typically contains additional "junk" columns. In particular, any junk columns that were requested by `AddForeignUpdateTargets` will be available from this slot.

The return value is either a slot containing the row as it was actually updated (this might differ from the data supplied, for example as a result of trigger actions), or `NULL` if no row was actually updated (again, typically as a result of triggers). The passed-in `slot` can be re-used for this purpose.

The data in the returned slot is used only if the `UPDATE` statement has a `RETURNING` clause or involves a view `WITH CHECK OPTION`; or if the foreign table has an `AFTER ROW` trigger. Triggers require all columns, but the FDW could choose to optimize away returning some or all columns depending on the contents of the `RETURNING` clause or `WITH CHECK OPTION` constraints. Regardless, some slot must be returned to indicate success, or the query's reported row count will be wrong.

If the `ExecForeignUpdate` pointer is set to `NULL`, attempts to update the foreign table will fail with an error message.

```
TupleTableSlot *
ExecForeignDelete(EState *estate,
                  ResultRelInfo *rinfo,
                  TupleTableSlot *slot,
                  TupleTableSlot *planSlot);
```

Delete one tuple from the foreign table. `estate` is global execution state for the query. `rinfo` is the `ResultRelInfo` struct describing the target foreign table. `slot` contains nothing useful upon call, but can be used to hold the returned tuple. `planSlot` contains the tuple that was generated by the `ModifyTable` plan node's subplan; in particular, it will carry any junk columns that were requested by `AddForeignUpdateTargets`. The junk column(s) must be used to identify the tuple to be deleted.

The return value is either a slot containing the row that was deleted, or `NULL` if no row was deleted (typically as a result of triggers). The passed-in `slot` can be used to hold the tuple to be returned.

The data in the returned slot is used only if the `DELETE` query has a `RETURNING` clause or the foreign table has an `AFTER ROW` trigger. Triggers require all columns, but the FDW could choose to optimize away returning some or all columns depending on the contents of the `RETURNING` clause. Regardless, some slot must be returned to indicate success, or the query's reported row count will be wrong.

If the `ExecForeignDelete` pointer is set to `NULL`, attempts to delete from the foreign table will fail with an error message.

```
void
EndForeignModify(EState *estate,
                 ResultRelInfo *rinfo);
```

End the table update and release resources. It is normally not important to release `palloc`'d memory, but for example open files and connections to remote servers should be cleaned up.

If the `EndForeignModify` pointer is set to `NULL`, no action is taken during executor shutdown.

Tuples inserted into a partitioned table by `INSERT` or `COPY FROM` are routed to partitions. If an FDW supports routable foreign-table partitions, it should also provide the following callback functions. These functions are also called when `COPY FROM` is executed on a foreign table.

```
void
BeginForeignInsert(ModifyTableState *mtstate,
                  ResultRelInfo *rinfo);
```

Begin executing an insert operation on a foreign table. This routine is called right before the first tuple is inserted into the foreign table in both cases when it is the partition chosen for tuple routing and the target specified in a `COPY FROM` command. It should perform any initialization needed prior to the actual insertion. Subsequently, `ExecForeignInsert` or `ExecForeignBatchInsert` will be called for tuple(s) to be inserted into the foreign table.

`mtstate` is the overall state of the `ModifyTable` plan node being executed; global data about the plan and execution state is available via this structure. `rinfo` is the `ResultRelInfo` struct describing the target foreign table. (The `ri_FdwState` field of `ResultRelInfo` is available for the FDW to store any private state it needs for this operation.)

When this is called by a `COPY FROM` command, the plan-related global data in `mtstate` is not provided and the `planSlot` parameter of `ExecForeignInsert` subsequently called for each inserted tuple is `NULL`, whether the foreign table is the partition chosen for tuple routing or the target specified in the command.

If the `BeginForeignInsert` pointer is set to `NULL`, no action is taken for the initialization.

Note that if the FDW does not support routable foreign-table partitions and/or executing `COPY FROM` on foreign tables, this function or `ExecForeignInsert`/`ExecForeignBatchInsert` subsequently called must throw error as needed.

```
void
EndForeignInsert(EState *estate,
                 ResultRelInfo *rinfo);
```

End the insert operation and release resources. It is normally not important to release `palloc`'d memory, but for example open files and connections to remote servers should be cleaned up.

If the `EndForeignInsert` pointer is set to `NULL`, no action is taken for the termination.

```
int
IsForeignRelUpdatable(Relation rel);
```

Report which update operations the specified foreign table supports. The return value should be a bit mask of rule event numbers indicating which operations are supported by the foreign table, using the `CmdType` enumeration; that is,  $(1 \ll \text{CMD\_UPDATE}) = 4$  for `UPDATE`,  $(1 \ll \text{CMD\_INSERT}) = 8$  for `INSERT`, and  $(1 \ll \text{CMD\_DELETE}) = 16$  for `DELETE`.

If the `IsForeignRelUpdatable` pointer is set to `NULL`, foreign tables are assumed to be insertable, updatable, or deletable if the FDW provides `ExecForeignInsert`, `ExecForeignUpdate`, or `ExecForeignDelete` respectively. This function is only needed if the FDW supports some tables that are updatable and some that are not. (Even then, it's permissible to throw an error in the execution routine instead

of checking in this function. However, this function is used to determine updatability for display in the `information_schema` views.)

Some inserts, updates, and deletes to foreign tables can be optimized by implementing an alternative set of interfaces. The ordinary interfaces for inserts, updates, and deletes fetch rows from the remote server and then modify those rows one at a time. In some cases, this row-by-row approach is necessary, but it can be inefficient. If it is possible for the foreign server to determine which rows should be modified without actually retrieving them, and if there are no local structures which would affect the operation (row-level local triggers, stored generated columns, or `WITH CHECK OPTION` constraints from parent views), then it is possible to arrange things so that the entire operation is performed on the remote server. The interfaces described below make this possible.

```
bool
PlanDirectModify(PlannerInfo *root,
                 ModifyTable *plan,
                 Index resultRelation,
                 int subplan_index);
```

Decide whether it is safe to execute a direct modification on the remote server. If so, return `true` after performing planning actions needed for that. Otherwise, return `false`. This optional function is called during query planning. If this function succeeds, `BeginDirectModify`, `IterateDirectModify` and `EndDirectModify` will be called at the execution stage, instead. Otherwise, the table modification will be executed using the table-updating functions described above. The parameters are the same as for `PlanForeignModify`.

To execute the direct modification on the remote server, this function must rewrite the target subplan with a `ForeignScan` plan node that executes the direct modification on the remote server. The `operation` and `resultRelation` fields of the `ForeignScan` must be set appropriately. `operation` must be set to the `CmdType` enumeration corresponding to the statement kind (that is, `CMD_UPDATE` for `UPDATE`, `CMD_INSERT` for `INSERT`, and `CMD_DELETE` for `DELETE`), and the `resultRelation` argument must be copied to the `resultRelation` field.

See [Section 57.4](#) for additional information.

If the `PlanDirectModify` pointer is set to `NULL`, no attempts to execute a direct modification on the remote server are taken.

```
void
BeginDirectModify(ForeignScanState *node,
                 int eflags);
```

Prepare to execute a direct modification on the remote server. This is called during executor startup. It should perform any initialization needed prior to the direct modification (that should be done upon the first call to `IterateDirectModify`). The `ForeignScanState` node has already been created, but its `fdw_state` field is still `NULL`. Information about the table to modify is accessible through the `ForeignScanState` node (in particular, from the underlying `ForeignScan` plan node, which contains any FDW-private information provided by `PlanDirectModify`). `eflags` contains flag bits describing the executor's operating mode for this plan node.

Note that when `(eflags & EXEC_FLAG_EXPLAIN_ONLY)` is true, this function should not perform any externally-visible actions; it should only do the minimum required to make the node state valid for `ExplainDirectModify` and `EndDirectModify`.

If the `BeginDirectModify` pointer is set to `NULL`, no attempts to execute a direct modification on the remote server are taken.

```
TupleTableSlot *
IterateDirectModify(ForeignScanState *node);
```

When the `INSERT`, `UPDATE` or `DELETE` query doesn't have a `RETURNING` clause, just return `NULL` after a direct modification on the remote server. When the query has the clause, fetch one result containing the

data needed for the `RETURNING` calculation, returning it in a tuple table slot (the node's `ScanTupleSlot` should be used for this purpose). The data that was actually inserted, updated or deleted must be stored in `node->resultRelInfo->ri_projectReturning->pi_exprContext->ecxt_scantuple`. Return `NULL` if no more rows are available. Note that this is called in a short-lived memory context that will be reset between invocations. Create a memory context in `BeginDirectModify` if you need longer-lived storage, or use the `es_query_cxt` of the node's `EState`.

The rows returned must match the `fdw_scan_tlist` target list if one was supplied, otherwise they must match the row type of the foreign table being updated. If you choose to optimize away fetching columns that are not needed for the `RETURNING` calculation, you should insert nulls in those column positions, or else generate a `fdw_scan_tlist` list with those columns omitted.

Whether the query has the clause or not, the query's reported row count must be incremented by the FDW itself. When the query doesn't have the clause, the FDW must also increment the row count for the `ForeignScanState` node in the `EXPLAIN ANALYZE` case.

If the `IterateDirectModify` pointer is set to `NULL`, no attempts to execute a direct modification on the remote server are taken.

```
void
EndDirectModify(ForeignScanState *node);
```

Clean up following a direct modification on the remote server. It is normally not important to release `palloc'd` memory, but for example open files and connections to the remote server should be cleaned up.

If the `EndDirectModify` pointer is set to `NULL`, no attempts to execute a direct modification on the remote server are taken.

### 57.2.5. FDW Routines for `TRUNCATE`

```
void
ExecForeignTruncate(List *rels,
                    DropBehavior behavior,
                    bool restart_seqs);
```

Truncate foreign tables. This function is called when `TRUNCATE` is executed on a foreign table. `rels` is a list of `Relation` data structures of foreign tables to truncate.

`behavior` is either `DROP_RESTRICT` or `DROP_CASCADE` indicating that the `RESTRICT` or `CASCADE` option was requested in the original `TRUNCATE` command, respectively.

If `restart_seqs` is `true`, the original `TRUNCATE` command requested the `RESTART IDENTITY` behavior, otherwise the `CONTINUE IDENTITY` behavior was requested.

Note that the `ONLY` options specified in the original `TRUNCATE` command are not passed to `ExecForeignTruncate`. This behavior is similar to the callback functions of `SELECT`, `UPDATE` and `DELETE` on a foreign table.

`ExecForeignTruncate` is invoked once per foreign server for which foreign tables are to be truncated. This means that all foreign tables included in `rels` must belong to the same server.

If the `ExecForeignTruncate` pointer is set to `NULL`, attempts to truncate foreign tables will fail with an error message.

### 57.2.6. FDW Routines for Row Locking

If an FDW wishes to support *late row locking* (as described in [Section 57.5](#)), it must provide the following callback functions:

```
RowMarkType
GetForeignRowMarkType(RangeTblEntry *rte,
```

```
LockClauseStrength strength);
```

Report which row-marking option to use for a foreign table. `rte` is the `RangeTblEntry` node for the table and `strength` describes the lock strength requested by the relevant `FOR UPDATE/SHARE` clause, if any. The result must be a member of the `RowMarkType` enum type.

This function is called during query planning for each foreign table that appears in an `UPDATE`, `DELETE`, or `SELECT FOR UPDATE/SHARE` query and is not the target of `UPDATE` or `DELETE`.

If the `GetForeignRowMarkType` pointer is set to `NULL`, the `ROW_MARK_COPY` option is always used. (This implies that `RefetchForeignRow` will never be called, so it need not be provided either.)

See [Section 57.5](#) for more information.

```
void
RefetchForeignRow(EState *estate,
                  ExecRowMark *erm,
                  Datum rowid,
                  TupleTableSlot *slot,
                  bool *updated);
```

Re-fetch one tuple slot from the foreign table, after locking it if required. `estate` is global execution state for the query. `erm` is the `ExecRowMark` struct describing the target foreign table and the row lock type (if any) to acquire. `rowid` identifies the tuple to be fetched. `slot` contains nothing useful upon call, but can be used to hold the returned tuple. `updated` is an output parameter.

This function should store the tuple into the provided slot, or clear it if the row lock couldn't be obtained. The row lock type to acquire is defined by `erm->markType`, which is the value previously returned by `GetForeignRowMarkType`. (`ROW_MARK_REFERENCE` means to just re-fetch the tuple without acquiring any lock, and `ROW_MARK_COPY` will never be seen by this routine.)

In addition, `*updated` should be set to `true` if what was fetched was an updated version of the tuple rather than the same version previously obtained. (If the FDW cannot be sure about this, always returning `true` is recommended.)

Note that by default, failure to acquire a row lock should result in raising an error; returning with an empty slot is only appropriate if the `SKIP LOCKED` option is specified by `erm->waitPolicy`.

The `rowid` is the `ctid` value previously read for the row to be re-fetched. Although the `rowid` value is passed as a `Datum`, it can currently only be a `tid`. The function API is chosen in hopes that it may be possible to allow other data types for row IDs in future.

If the `RefetchForeignRow` pointer is set to `NULL`, attempts to re-fetch rows will fail with an error message.

See [Section 57.5](#) for more information.

```
bool
RecheckForeignScan(ForeignScanState *node,
                  TupleTableSlot *slot);
```

Recheck that a previously-returned tuple still matches the relevant scan and join qualifiers, and possibly provide a modified version of the tuple. For foreign data wrappers which do not perform join pushdown, it will typically be more convenient to set this to `NULL` and instead set `fdw_recheck_qual` appropriately. When outer joins are pushed down, however, it isn't sufficient to reapply the checks relevant to all the base tables to the result tuple, even if all needed attributes are present, because failure to match some qualifier might result in some attributes going to `NULL`, rather than in no tuple being returned. `RecheckForeignScan` can recheck qualifiers and return `true` if they are still satisfied and `false` otherwise, but it can also store a replacement tuple into the supplied slot.

To implement join pushdown, a foreign data wrapper will typically construct an alternative local join plan which is used only for rechecks; this will become the outer subplan of the `ForeignScan`. When a recheck

is required, this subplan can be executed and the resulting tuple can be stored in the slot. This plan need not be efficient since no base table will return more than one row; for example, it may implement all joins as nested loops. The function `GetExistingLocalJoinPath` may be used to search existing paths for a suitable local join path, which can be used as the alternative local join plan. `GetExistingLocalJoinPath` searches for an unparameterized path in the path list of the specified join relation. (If it does not find such a path, it returns `NULL`, in which case a foreign data wrapper may build the local path by itself or may choose not to create access paths for that join.)

### 57.2.7. FDW Routines for EXPLAIN

```
void
ExplainForeignScan(ForeignScanState *node,
                   ExplainState *es);
```

Print additional `EXPLAIN` output for a foreign table scan. This function can call `ExplainPropertyText` and related functions to add fields to the `EXPLAIN` output. The flag fields in `es` can be used to determine what to print, and the state of the `ForeignScanState` node can be inspected to provide run-time statistics in the `EXPLAIN ANALYZE` case.

If the `ExplainForeignScan` pointer is set to `NULL`, no additional information is printed during `EXPLAIN`.

```
void
ExplainForeignModify(ModifyTableState *mtstate,
                    ResultRelInfo *rinfo,
                    List *fdw_private,
                    int subplan_index,
                    struct ExplainState *es);
```

Print additional `EXPLAIN` output for a foreign table update. This function can call `ExplainPropertyText` and related functions to add fields to the `EXPLAIN` output. The flag fields in `es` can be used to determine what to print, and the state of the `ModifyTableState` node can be inspected to provide run-time statistics in the `EXPLAIN ANALYZE` case. The first four arguments are the same as for `BeginForeignModify`.

If the `ExplainForeignModify` pointer is set to `NULL`, no additional information is printed during `EXPLAIN`.

```
void
ExplainDirectModify(ForeignScanState *node,
                   ExplainState *es);
```

Print additional `EXPLAIN` output for a direct modification on the remote server. This function can call `ExplainPropertyText` and related functions to add fields to the `EXPLAIN` output. The flag fields in `es` can be used to determine what to print, and the state of the `ForeignScanState` node can be inspected to provide run-time statistics in the `EXPLAIN ANALYZE` case.

If the `ExplainDirectModify` pointer is set to `NULL`, no additional information is printed during `EXPLAIN`.

### 57.2.8. FDW Routines for ANALYZE

```
bool
AnalyzeForeignTable(Relation relation,
                   AcquireSampleRowsFunc *func,
                   BlockNumber *totalpages);
```

This function is called when `ANALYZE` is executed on a foreign table. If the FDW can collect statistics for this foreign table, it should return `true`, and provide a pointer to a function that will collect sample rows from the table in `func`, plus the estimated size of the table in pages in `totalpages`. Otherwise, return `false`.

If the FDW does not support collecting statistics for any tables, the `AnalyzeForeignTable` pointer can be set to `NULL`.

If provided, the sample collection function must have the signature

```
int
AcquireSampleRowsFunc(Relation relation,
                      int elevel,
                      HeapTuple *rows,
                      int targrows,
                      double *totalrows,
                      double *totaldeadrows);
```

A random sample of up to *targrows* rows should be collected from the table and stored into the caller-provided *rows* array. The actual number of rows collected must be returned. In addition, store estimates of the total numbers of live and dead rows in the table into the output parameters *totalrows* and *totaldeadrows*. (Set *totaldeadrows* to zero if the FDW does not have any concept of dead rows.)

### 57.2.9. FDW Routines for IMPORT FOREIGN SCHEMA

```
List *
ImportForeignSchema(ImportForeignSchemaStmt *stmt, Oid serverOid);
```

Obtain a list of foreign table creation commands. This function is called when executing [IMPORT FOREIGN SCHEMA](#), and is passed the parse tree for that statement, as well as the OID of the foreign server to use. It should return a list of C strings, each of which must contain a [CREATE FOREIGN TABLE](#) command. These strings will be parsed and executed by the core server.

Within the `ImportForeignSchemaStmt` struct, `remote_schema` is the name of the remote schema from which tables are to be imported. `list_type` identifies how to filter table names: `FDW_IMPORT_SCHEMA_ALL` means that all tables in the remote schema should be imported (in this case `table_list` is empty), `FDW_IMPORT_SCHEMA_LIMIT_TO` means to include only tables listed in `table_list`, and `FDW_IMPORT_SCHEMA_EXCEPT` means to exclude the tables listed in `table_list`. `options` is a list of options used for the import process. The meanings of the options are up to the FDW. For example, an FDW could use an option to define whether the `NOT NULL` attributes of columns should be imported. These options need not have anything to do with those supported by the FDW as database object options.

The FDW may ignore the `local_schema` field of the `ImportForeignSchemaStmt`, because the core server will automatically insert that name into the parsed `CREATE FOREIGN TABLE` commands.

The FDW does not have to concern itself with implementing the filtering specified by `list_type` and `table_list`, either, as the core server will automatically skip any returned commands for tables excluded according to those options. However, it's often useful to avoid the work of creating commands for excluded tables in the first place. The function `IsImportableForeignTable()` may be useful to test whether a given foreign-table name will pass the filter.

If the FDW does not support importing table definitions, the `ImportForeignSchema` pointer can be set to `NULL`.

### 57.2.10. FDW Routines for Parallel Execution

A `ForeignScan` node can, optionally, support parallel execution. A parallel `ForeignScan` will be executed in multiple processes and must return each row exactly once across all cooperating processes. To do this, processes can coordinate through fixed-size chunks of dynamic shared memory. This shared memory is not guaranteed to be mapped at the same address in every process, so it must not contain pointers. The following functions are all optional, but most are required if parallel execution is to be supported.

```
bool
IsForeignScanParallelSafe(PlannerInfo *root, RelOptInfo *rel,
                          RangeTblEntry *rte);
```

Test whether a scan can be performed within a parallel worker. This function will only be called when the planner believes that a parallel plan might be possible, and should return true if it is safe for that scan to run within a parallel worker. This will generally not be the case if the remote data source has transaction semantics, unless the worker's connection to the data can somehow be made to share the same transaction context as the leader.

If this function is not defined, it is assumed that the scan must take place within the parallel leader. Note that returning true does not mean that the scan itself can be done in parallel, only that the scan can be performed within a parallel worker. Therefore, it can be useful to define this method even when parallel execution is not supported.

Size

```
EstimateDSMForeignScan(ForeignScanState *node, ParallelContext *pcxt);
```

Estimate the amount of dynamic shared memory that will be required for parallel operation. This may be higher than the amount that will actually be used, but it must not be lower. The return value is in bytes. This function is optional, and can be omitted if not needed; but if it is omitted, the next three functions must be omitted as well, because no shared memory will be allocated for the FDW's use.

void

```
InitializeDSMForeignScan(ForeignScanState *node, ParallelContext *pcxt,  
                        void *coordinate);
```

Initialize the dynamic shared memory that will be required for parallel operation. `coordinate` points to a shared memory area of size equal to the return value of `EstimateDSMForeignScan`. This function is optional, and can be omitted if not needed.

void

```
ReInitializeDSMForeignScan(ForeignScanState *node, ParallelContext *pcxt,  
                          void *coordinate);
```

Re-initialize the dynamic shared memory required for parallel operation when the foreign-scan plan node is about to be re-scanned. This function is optional, and can be omitted if not needed. Recommended practice is that this function reset only shared state, while the `ReScanForeignScan` function resets only local state. Currently, this function will be called before `ReScanForeignScan`, but it's best not to rely on that ordering.

void

```
InitializeWorkerForeignScan(ForeignScanState *node, shm_toc *toc,  
                          void *coordinate);
```

Initialize a parallel worker's local state based on the shared state set up by the leader during `InitializeDSMForeignScan`. This function is optional, and can be omitted if not needed.

void

```
ShutdownForeignScan(ForeignScanState *node);
```

Release resources when it is anticipated the node will not be executed to completion. This is not called in all cases; sometimes, `EndForeignScan` may be called without this function having been called first. Since the DSM segment used by parallel query is destroyed just after this callback is invoked, foreign data wrappers that wish to take some action before the DSM segment goes away should implement this method.

## 57.2.11. FDW Routines for Asynchronous Execution

A `ForeignScan` node can, optionally, support asynchronous execution. The following functions are all optional, but are all required if asynchronous execution is to be supported.

bool

```
IsForeignPathAsyncCapable(ForeignPath *path);
```

Test whether a given `ForeignPath` `path` can scan the underlying foreign relation asynchronously. This function will only be called at the end of query planning when the given path is a direct child of an `AppendPath` path and when the planner believes that asynchronous execution improves performance, and should return true if the given path is able to scan the foreign relation asynchronously.

If this function is not defined, it is assumed that the given path scans the foreign relation using `IterateForeignScan`. (This implies that the callback functions described below will never be called, so they need not be provided either.)

```
void
ForeignAsyncRequest (AsyncRequest *areq);
```

Produce one tuple asynchronously from the `ForeignScan` node. `areq` is the `AsyncRequest` struct describing the `ForeignScan` node and the parent `Append` node that requested the tuple from it. This function should store the tuple into the slot specified by `areq->result`, and set `areq->request_complete` to `true`; or if it needs to wait on an event external to the core server such as network I/O, and cannot produce any tuple immediately, set the flag to `false`, and set `areq->callback_pending` to `true` for the `ForeignScan` node to get a callback from the callback functions described below. If no more tuples are available, set the slot to `NULL` or an empty slot, and the `areq->request_complete` flag to `true`. It's recommended to use `ExecAsyncRequestDone` or `ExecAsyncRequestPending` to set the output parameters in the `areq`.

```
void
ForeignAsyncConfigureWait (AsyncRequest *areq);
```

Configure a file descriptor event for which the `ForeignScan` node wishes to wait. This function will only be called when the `ForeignScan` node has the `areq->callback_pending` flag set, and should add the event to the `as_eventset` of the parent `Append` node described by the `areq`. When the file descriptor event occurs, `ForeignAsyncNotify` will be called.

```
void
ForeignAsyncNotify (AsyncRequest *areq);
```

Process a relevant event that has occurred, then produce one tuple asynchronously from the `ForeignScan` node. This function should set the output parameters in the `areq` in the same way as `ForeignAsyncRequest`.

## 57.2.12. FDW Routines for Reparameterization of Paths

```
List *
ReparameterizeForeignPathByChild (PlannerInfo *root, List *fdw_private,
                                  RelOptInfo *child_rel);
```

This function is called while converting a path parameterized by the top-most parent of the given child relation `child_rel` to be parameterized by the child relation. The function is used to reparameterize any paths or translate any expression nodes saved in the given `fdw_private` member of a `ForeignPath`. The callback may use `reparameterize_path_by_child`, `adjust_appendrel_attrs` or `adjust_appendrel_attrs_multilevel` as required.

## 57.3. Foreign Data Wrapper Helper Functions

Several helper functions are exported from the core server so that authors of foreign data wrappers can get easy access to attributes of FDW-related objects, such as FDW options. To use any of these functions, you need to include the header file [foreign/foreign.h](#) in your source file. That header also defines the struct types that are returned by these functions.

```
ForeignDataWrapper *
GetForeignDataWrapperExtended (Oid fdwid, bits16 flags);
```

This function returns a `ForeignDataWrapper` object for the foreign-data wrapper with the given OID. A `ForeignDataWrapper` object contains properties of the FDW (see [foreign/foreign.h](#) for details). `flags` is a bitwise-or'd bit mask indicating an extra set of options. It can take the value `FDW_MISSING_OK`, in which case a `NULL` result is returned to the caller instead of an error for an undefined object.

```
ForeignDataWrapper *
GetForeignDataWrapper (Oid fdwid);
```

This function returns a `ForeignDataWrapper` object for the foreign-data wrapper with the given OID. A `ForeignDataWrapper` object contains properties of the FDW (see [foreign/foreign.h](#) for details).

```
ForeignServer *
GetForeignServerExtended (Oid serverid, bits16 flags);
```

This function returns a `ForeignServer` object for the foreign server with the given OID. A `ForeignServer` object contains properties of the server (see `foreign/foreign.h` for details). `flags` is a bitwise-or'd bit mask indicating an extra set of options. It can take the value `FSV_MISSING_OK`, in which case a `NULL` result is returned to the caller instead of an error for an undefined object.

```
ForeignServer *
GetForeignServer(Oid serverid);
```

This function returns a `ForeignServer` object for the foreign server with the given OID. A `ForeignServer` object contains properties of the server (see `foreign/foreign.h` for details).

```
UserMapping *
GetUserMapping(Oid userid, Oid serverid);
```

This function returns a `UserMapping` object for the user mapping of the given role on the given server. (If there is no mapping for the specific user, it will return the mapping for `PUBLIC`, or throw error if there is none.) A `UserMapping` object contains properties of the user mapping (see `foreign/foreign.h` for details).

```
ForeignTable *
GetForeignTable(Oid relid);
```

This function returns a `ForeignTable` object for the foreign table with the given OID. A `ForeignTable` object contains properties of the foreign table (see `foreign/foreign.h` for details).

```
List *
GetForeignColumnOptions(Oid relid, AttrNumber attnum);
```

This function returns the per-column FDW options for the column with the given foreign table OID and attribute number, in the form of a list of `DefElem`. `NIL` is returned if the column has no options.

Some object types have name-based lookup functions in addition to the OID-based ones:

```
ForeignDataWrapper *
GetForeignDataWrapperByName(const char *name, bool missing_ok);
```

This function returns a `ForeignDataWrapper` object for the foreign-data wrapper with the given name. If the wrapper is not found, return `NULL` if `missing_ok` is true, otherwise raise an error.

```
ForeignServer *
GetForeignServerByName(const char *name, bool missing_ok);
```

This function returns a `ForeignServer` object for the foreign server with the given name. If the server is not found, return `NULL` if `missing_ok` is true, otherwise raise an error.

## 57.4. Foreign Data Wrapper Query Planning

The FDW callback functions `GetForeignRelSize`, `GetForeignPaths`, `GetForeignPlan`, `PlanForeignModify`, `GetForeignJoinPaths`, `GetForeignUpperPaths`, and `PlanDirectModify` must fit into the workings of the Postgres Pro planner. Here are some notes about what they must do.

The information in `root` and `baserel` can be used to reduce the amount of information that has to be fetched from the foreign table (and therefore reduce the cost). `baserel->baserestrictinfo` is particularly interesting, as it contains restriction quals (`WHERE` clauses) that should be used to filter the rows to be fetched. (The FDW itself is not required to enforce these quals, as the core executor can check them instead.) `baserel->reltarget->exprs` can be used to determine which columns need to be fetched; but note that it only lists columns that have to be emitted by the `ForeignScan` plan node, not columns that are used in qual evaluation but not output by the query.

Various private fields are available for the FDW planning functions to keep information in. Generally, whatever you store in FDW private fields should be `palloc'd`, so that it will be reclaimed at the end of planning.

`baserel->fdw_private` is a void pointer that is available for FDW planning functions to store information relevant to the particular foreign table. The core planner does not touch it except to initialize it to NULL when the `RelOptInfo` node is created. It is useful for passing information forward from `GetForeignRelSize` to `GetForeignPaths` and/or `GetForeignPaths` to `GetForeignPlan`, thereby avoiding recalculation.

`GetForeignPaths` can identify the meaning of different access paths by storing private information in the `fdw_private` field of `ForeignPath` nodes. `fdw_private` is declared as a `List` pointer, but could actually contain anything since the core planner does not touch it. However, best practice is to use a representation that's dumpable by `nodeToString`, for use with debugging support available in the backend.

`GetForeignPlan` can examine the `fdw_private` field of the selected `ForeignPath` node, and can generate `fdw_exprs` and `fdw_private` lists to be placed in the `ForeignScan` plan node, where they will be available at execution time. Both of these lists must be represented in a form that `copyObject` knows how to copy. The `fdw_private` list has no other restrictions and is not interpreted by the core backend in any way. The `fdw_exprs` list, if not NIL, is expected to contain expression trees that are intended to be executed at run time. These trees will undergo post-processing by the planner to make them fully executable.

In `GetForeignPlan`, generally the passed-in target list can be copied into the plan node as-is. The passed `scan_clauses` list contains the same clauses as `baserel->baserestrictinfo`, but may be re-ordered for better execution efficiency. In simple cases the FDW can just strip `RestrictInfo` nodes from the `scan_clauses` list (using `extract_actual_clauses`) and put all the clauses into the plan node's qual list, which means that all the clauses will be checked by the executor at run time. More complex FDWs may be able to check some of the clauses internally, in which case those clauses can be removed from the plan node's qual list so that the executor doesn't waste time rechecking them.

As an example, the FDW might identify some restriction clauses of the form `foreign_variable = sub_expression`, which it determines can be executed on the remote server given the locally-evaluated value of the `sub_expression`. The actual identification of such a clause should happen during `GetForeignPaths`, since it would affect the cost estimate for the path. The path's `fdw_private` field would probably include a pointer to the identified clause's `RestrictInfo` node. Then `GetForeignPlan` would remove that clause from `scan_clauses`, but add the `sub_expression` to `fdw_exprs` to ensure that it gets massaged into executable form. It would probably also put control information into the plan node's `fdw_private` field to tell the execution functions what to do at run time. The query transmitted to the remote server would involve something like `WHERE foreign_variable = $1`, with the parameter value obtained at run time from evaluation of the `fdw_exprs` expression tree.

Any clauses removed from the plan node's qual list must instead be added to `fdw_recheckquals` or rechecked by `RecheckForeignScan` in order to ensure correct behavior at the `READ COMMITTED` isolation level. When a concurrent update occurs for some other table involved in the query, the executor may need to verify that all of the original quals are still satisfied for the tuple, possibly against a different set of parameter values. Using `fdw_recheckquals` is typically easier than implementing checks inside `RecheckForeignScan`, but this method will be insufficient when outer joins have been pushed down, since the join tuples in that case might have some fields go to NULL without rejecting the tuple entirely.

Another `ForeignScan` field that can be filled by FDWs is `fdw_scan_tlist`, which describes the tuples returned by the FDW for this plan node. For simple foreign table scans this can be set to NIL, implying that the returned tuples have the row type declared for the foreign table. A non-NIL value must be a target list (list of `TargetEntry`s) containing Vars and/or expressions representing the returned columns. This might be used, for example, to show that the FDW has omitted some columns that it noticed won't be needed for the query. Also, if the FDW can compute expressions used by the query more cheaply than can be done locally, it could add those expressions to `fdw_scan_tlist`. Note that join plans (created from paths made by `GetForeignJoinPaths`) must always supply `fdw_scan_tlist` to describe the set of columns they will return.

The FDW should always construct at least one path that depends only on the table's restriction clauses. In join queries, it might also choose to construct path(s) that depend on join clauses, for example `foreign_variable = local_variable`. Such clauses will not be found in `baserel->baserestrictinfo` but

must be sought in the relation's join lists. A path using such a clause is called a “parameterized path”. It must identify the other relations used in the selected join clause(s) with a suitable value of `param_info`; use `get_baserel_parampathinfo` to compute that value. In `GetForeignPlan`, the *local\_variable* portion of the join clause would be added to `fdw_exprs`, and then at run time the case works the same as for an ordinary restriction clause.

If an FDW supports remote joins, `GetForeignJoinPaths` should produce `ForeignPaths` for potential remote joins in much the same way as `GetForeignPaths` works for base tables. Information about the intended join can be passed forward to `GetForeignPlan` in the same ways described above. However, `baserestrictinfo` is not relevant for join relations; instead, the relevant join clauses for a particular join are passed to `GetForeignJoinPaths` as a separate parameter (`extra->restrictlist`).

An FDW might additionally support direct execution of some plan actions that are above the level of scans and joins, such as grouping or aggregation. To offer such options, the FDW should generate paths and insert them into the appropriate *upper relation*. For example, a path representing remote aggregation should be inserted into the `UPPERREL_GROUP_AGG` relation, using `add_path`. This path will be compared on a cost basis with local aggregation performed by reading a simple scan path for the foreign relation (note that such a path must also be supplied, else there will be an error at plan time). If the remote-aggregation path wins, which it usually would, it will be converted into a plan in the usual way, by calling `GetForeignPlan`. The recommended place to generate such paths is in the `GetForeignUpperPaths` callback function, which is called for each upper relation (i.e., each post-scan/join processing step), if all the base relations of the query come from the same FDW.

`PlanForeignModify` and the other callbacks described in [Section 57.2.4](#) are designed around the assumption that the foreign relation will be scanned in the usual way and then individual row updates will be driven by a local `ModifyTable` plan node. This approach is necessary for the general case where an update requires reading local tables as well as foreign tables. However, if the operation could be executed entirely by the foreign server, the FDW could generate a path representing that and insert it into the `UPPERREL_FINAL` upper relation, where it would compete against the `ModifyTable` approach. This approach could also be used to implement remote `SELECT FOR UPDATE`, rather than using the row locking callbacks described in [Section 57.2.6](#). Keep in mind that a path inserted into `UPPERREL_FINAL` is responsible for implementing *all* behavior of the query.

When planning an `UPDATE` or `DELETE`, `PlanForeignModify` and `PlanDirectModify` can look up the `RelOptInfo` struct for the foreign table and make use of the `baserel->fdw_private` data previously created by the scan-planning functions. However, in `INSERT` the target table is not scanned so there is no `RelOptInfo` for it. The `List` returned by `PlanForeignModify` has the same restrictions as the `fdw_private` list of a `ForeignScan` plan node, that is it must contain only structures that `copyObject` knows how to copy.

`INSERT` with an `ON CONFLICT` clause does not support specifying the conflict target, as unique constraints or exclusion constraints on remote tables are not locally known. This in turn implies that `ON CONFLICT DO UPDATE` is not supported, since the specification is mandatory there.

## 57.5. Row Locking in Foreign Data Wrappers

If an FDW's underlying storage mechanism has a concept of locking individual rows to prevent concurrent updates of those rows, it is usually worthwhile for the FDW to perform row-level locking with as close an approximation as practical to the semantics used in ordinary Postgres Pro tables. There are multiple considerations involved in this.

One key decision to be made is whether to perform *early locking* or *late locking*. In early locking, a row is locked when it is first retrieved from the underlying store, while in late locking, the row is locked only when it is known that it needs to be locked. (The difference arises because some rows may be discarded by locally-checked restriction or join conditions.) Early locking is much simpler and avoids extra round trips to a remote store, but it can cause locking of rows that need not have been locked, resulting in reduced concurrency or even unexpected deadlocks. Also, late locking is only possible if the row to be locked can be uniquely re-identified later. Preferably the row identifier should identify a specific version of the row, as Postgres Pro TIDs do.

By default, Postgres Pro ignores locking considerations when interfacing to FDWs, but an FDW can perform early locking without any explicit support from the core code. The API functions described in [Section 57.2.6](#), which were added in Postgres Pro 9.5, allow an FDW to use late locking if it wishes.

An additional consideration is that in `READ COMMITTED` isolation mode, Postgres Pro may need to re-check restriction and join conditions against an updated version of some target tuple. Rechecking join conditions requires re-obtaining copies of the non-target rows that were previously joined to the target tuple. When working with standard Postgres Pro tables, this is done by including the TIDs of the non-target tables in the column list projected through the join, and then re-fetching non-target rows when required. This approach keeps the join data set compact, but it requires inexpensive re-fetch capability, as well as a TID that can uniquely identify the row version to be re-fetched. By default, therefore, the approach used with foreign tables is to include a copy of the entire row fetched from a foreign table in the column list projected through the join. This puts no special demands on the FDW but can result in reduced performance of merge and hash joins. An FDW that is capable of meeting the re-fetch requirements can choose to do it the first way.

For an `UPDATE` or `DELETE` on a foreign table, it is recommended that the `ForeignScan` operation on the target table perform early locking on the rows that it fetches, perhaps via the equivalent of `SELECT FOR UPDATE`. An FDW can detect whether a table is an `UPDATE/DELETE` target at plan time by comparing its `relid` to `root->parse->resultRelation`, or at execution time by using `ExecRelationIsTargetRelation()`. An alternative possibility is to perform late locking within the `ExecForeignUpdate` or `ExecForeignDelete` callback, but no special support is provided for this.

For foreign tables that are specified to be locked by a `SELECT FOR UPDATE/SHARE` command, the `ForeignScan` operation can again perform early locking by fetching tuples with the equivalent of `SELECT FOR UPDATE/SHARE`. To perform late locking instead, provide the callback functions defined in [Section 57.2.6](#). In `GetForeignRowMarkType`, select rowmark option `ROW_MARK_EXCLUSIVE`, `ROW_MARK_NOKEYEXCLUSIVE`, `ROW_MARK_SHARE`, or `ROW_MARK_KEYSHARE` depending on the requested lock strength. (The core code will act the same regardless of which of these four options you choose.) Elsewhere, you can detect whether a foreign table was specified to be locked by this type of command by using `get_plan_rowmark` at plan time, or `ExecFindRowMark` at execution time; you must check not only whether a non-null rowmark struct is returned, but that its `strength` field is not `LCS_NONE`.

Lastly, for foreign tables that are used in an `UPDATE`, `DELETE` or `SELECT FOR UPDATE/SHARE` command but are not specified to be row-locked, you can override the default choice to copy entire rows by having `GetForeignRowMarkType` select option `ROW_MARK_REFERENCE` when it sees lock strength `LCS_NONE`. This will cause `RefetchForeignRow` to be called with that value for `markType`; it should then re-fetch the row without acquiring any new lock. (If you have a `GetForeignRowMarkType` function but don't wish to re-fetch unlocked rows, select option `ROW_MARK_COPY` for `LCS_NONE`.)

---

# Chapter 58. Writing a Table Sampling Method

Postgres Pro's implementation of the `TABLESAMPLE` clause supports custom table sampling methods, in addition to the `BERNOULLI` and `SYSTEM` methods that are required by the SQL standard. The sampling method determines which rows of the table will be selected when the `TABLESAMPLE` clause is used.

At the SQL level, a table sampling method is represented by a single SQL function, typically implemented in C, having the signature

```
method_name(internal) RETURNS tsm_handler
```

The name of the function is the same method name appearing in the `TABLESAMPLE` clause. The `internal` argument is a dummy (always having value zero) that simply serves to prevent this function from being called directly from an SQL command. The result of the function must be a palloc'd struct of type `TsmRoutine`, which contains pointers to support functions for the sampling method. These support functions are plain C functions and are not visible or callable at the SQL level. The support functions are described in [Section 58.1](#).

In addition to function pointers, the `TsmRoutine` struct must provide these additional fields:

```
List *parameterTypes
```

This is an OID list containing the data type OIDs of the parameter(s) that will be accepted by the `TABLESAMPLE` clause when this sampling method is used. For example, for the built-in methods, this list contains a single item with value `FLOAT4OID`, which represents the sampling percentage. Custom sampling methods can have more or different parameters.

```
bool repeatable_across_queries
```

If `true`, the sampling method can deliver identical samples across successive queries, if the same parameters and `REPEATABLE` seed value are supplied each time and the table contents have not changed. When this is `false`, the `REPEATABLE` clause is not accepted for use with the sampling method.

```
bool repeatable_across_scans
```

If `true`, the sampling method can deliver identical samples across successive scans in the same query (assuming unchanging parameters, seed value, and snapshot). When this is `false`, the planner will not select plans that would require scanning the sampled table more than once, since that might result in inconsistent query output.

The table sampling methods included in the standard distribution are good references when trying to write your own. Look into the `contrib` subdirectory for add-on methods.

## 58.1. Sampling Method Support Functions

The TSM handler function returns a palloc'd `TsmRoutine` struct containing pointers to the support functions described below. Most of the functions are required, but some are optional, and those pointers can be `NULL`.

```
void
SampleScanGetSampleSize (PlannerInfo *root,
                        RelOptInfo *baserel,
                        List *paramexprs,
                        BlockNumber *pages,
                        double *tuples);
```

This function is called during planning. It must estimate the number of relation pages that will be read during a sample scan, and the number of tuples that will be selected by the scan. (For example, these

might be determined by estimating the sampling fraction, and then multiplying the `basere1->pages` and `basere1->tuples` numbers by that, being sure to round the results to integral values.) The `paramexprs` list holds the expression(s) that are parameters to the `TABLESAMPLE` clause. It is recommended to use `estimate_expression_value()` to try to reduce these expressions to constants, if their values are needed for estimation purposes; but the function must provide size estimates even if they cannot be reduced, and it should not fail even if the values appear invalid (remember that they're only estimates of what the run-time values will be). The `pages` and `tuples` parameters are outputs.

```
void
InitSampleScan (SampleScanState *node,
                int eflags);
```

Initialize for execution of a `SampleScan` plan node. This is called during executor startup. It should perform any initialization needed before processing can start. The `SampleScanState` node has already been created, but its `tsm_state` field is `NULL`. The `InitSampleScan` function can `palloc` whatever internal state data is needed by the sampling method, and store a pointer to it in `node->tsm_state`. Information about the table to scan is accessible through other fields of the `SampleScanState` node (but note that the `node->ss.ss_currentScanDesc` scan descriptor is not set up yet). `eflags` contains flag bits describing the executor's operating mode for this plan node.

When `(eflags & EXEC_FLAG_EXPLAIN_ONLY)` is true, the scan will not actually be performed, so this function should only do the minimum required to make the node state valid for `EXPLAIN` and `EndSampleScan`.

This function can be omitted (set the pointer to `NULL`), in which case `BeginSampleScan` must perform all initialization needed by the sampling method.

```
void
BeginSampleScan (SampleScanState *node,
                 Datum *params,
                 int nparams,
                 uint32 seed);
```

Begin execution of a sampling scan. This is called just before the first attempt to fetch a tuple, and may be called again if the scan needs to be restarted. Information about the table to scan is accessible through fields of the `SampleScanState` node (but note that the `node->ss.ss_currentScanDesc` scan descriptor is not set up yet). The `params` array, of length `nparams`, contains the values of the parameters supplied in the `TABLESAMPLE` clause. These will have the number and types specified in the sampling method's `parameterTypes` list, and have been checked to not be null. `seed` contains a seed to use for any random numbers generated within the sampling method; it is either a hash derived from the `REPEATABLE` value if one was given, or the result of `random()` if not.

This function may adjust the fields `node->use_bulkread` and `node->use_pagemode`. If `node->use_bulkread` is true, which it is by default, the scan will use a buffer access strategy that encourages recycling buffers after use. It might be reasonable to set this to false if the scan will visit only a small fraction of the table's pages. If `node->use_pagemode` is true, which it is by default, the scan will perform visibility checking in a single pass for all tuples on each visited page. It might be reasonable to set this to false if the scan will select only a small fraction of the tuples on each visited page. That will result in fewer tuple visibility checks being performed, though each one will be more expensive because it will require more locking.

If the sampling method is marked `repeatable_across_scans`, it must be able to select the same set of tuples during a rescan as it did originally, that is a fresh call of `BeginSampleScan` must lead to selecting the same tuples as before (if the `TABLESAMPLE` parameters and seed don't change).

```
BlockNumber
NextSampleBlock (SampleScanState *node, BlockNumber nblocks);
```

Returns the block number of the next page to be scanned, or `InvalidBlockNumber` if no pages remain to be scanned.

This function can be omitted (set the pointer to NULL), in which case the core code will perform a sequential scan of the entire relation. Such a scan can use synchronized scanning, so that the sampling method cannot assume that the relation pages are visited in the same order on each scan.

```
OffsetNumber  
NextSampleTuple (SampleScanState *node,  
                 BlockNumber blockno,  
                 OffsetNumber maxoffset);
```

Returns the offset number of the next tuple to be sampled on the specified page, or `InvalidOffsetNumber` if no tuples remain to be sampled. `maxoffset` is the largest offset number in use on the page.

### Note

`NextSampleTuple` is not explicitly told which of the offset numbers in the range `1 .. maxoffset` actually contain valid tuples. This is not normally a problem since the core code ignores requests to sample missing or invisible tuples; that should not result in any bias in the sample. However, if necessary, the function can use `node->donetuples` to examine how many of the tuples it returned were valid and visible.

### Note

`NextSampleTuple` must *not* assume that `blockno` is the same page number returned by the most recent `NextSampleBlock` call. It was returned by some previous `NextSampleBlock` call, but the core code is allowed to call `NextSampleBlock` in advance of actually scanning pages, so as to support prefetching. It is OK to assume that once sampling of a given page begins, successive `NextSampleTuple` calls all refer to the same page until `InvalidOffsetNumber` is returned.

```
void  
EndSampleScan (SampleScanState *node);
```

End the scan and release resources. It is normally not important to release `palloc'd` memory, but any externally-visible resources should be cleaned up. This function can be omitted (set the pointer to NULL) in the common case where no such resources exist.

---

# Chapter 59. Writing a Custom Scan Provider

Postgres Pro supports a set of experimental facilities which are intended to allow extension modules to add new scan types to the system. Unlike a [foreign data wrapper](#), which is only responsible for knowing how to scan its own foreign tables, a custom scan provider can provide an alternative method of scanning any relation in the system. Typically, the motivation for writing a custom scan provider will be to allow the use of some optimization not supported by the core system, such as caching or some form of hardware acceleration. This chapter outlines how to write a new custom scan provider.

Implementing a new type of custom scan is a three-step process. First, during planning, it is necessary to generate access paths representing a scan using the proposed strategy. Second, if one of those access paths is selected by the planner as the optimal strategy for scanning a particular relation, the access path must be converted to a plan. Finally, it must be possible to execute the plan and generate the same results that would have been generated for any other access path targeting the same relation.

## 59.1. Creating Custom Scan Paths

A custom scan provider will typically add paths for a base relation by setting the following hook, which is called after the core code has generated all the access paths it can for the relation (except for Gather paths, which are made after this call so that they can use partial paths added by the hook):

```
typedef void (*set_rel_pathlist_hook_type) (PlannerInfo *root,
                                           RelOptInfo *rel,
                                           Index rti,
                                           RangeTblEntry *rte);

extern PGDLLIMPORT set_rel_pathlist_hook_type set_rel_pathlist_hook;
```

Although this hook function can be used to examine, modify, or remove paths generated by the core system, a custom scan provider will typically confine itself to generating `CustomPath` objects and adding them to `rel` using `add_path`. The custom scan provider is responsible for initializing the `CustomPath` object, which is declared like this:

```
typedef struct CustomPath
{
    Path      path;
    uint32    flags;
    List      *custom_paths;
    List      *custom_private;
    const CustomPathMethods *methods;
} CustomPath;
```

`path` must be initialized as for any other path, including the row-count estimate, start and total cost, and sort ordering provided by this path. `flags` is a bit mask, which should include `CUSTOMPATH_SUPPORT_BACKWARD_SCAN` if the custom path can support a backward scan and `CUSTOMPATH_SUPPORT_MARK_RESTORE` if it can support mark and restore. Both capabilities are optional. An optional `custom_paths` is a list of `Path` nodes used by this custom-path node; these will be transformed into `Plan` nodes by planner. `custom_private` can be used to store the custom path's private data. Private data should be stored in a form that can be handled by `nodeToString`, so that debugging routines that attempt to print the custom path will work as designed. `methods` must point to a (usually statically allocated) object implementing the required custom path methods, which are further detailed below.

A custom scan provider can also provide join paths. Just as for base relations, such a path must produce the same output as would normally be produced by the join it replaces. To do this, the join provider should set the following hook, and then within the hook function, create `CustomPath` path(s) for the join relation.

```
typedef void (*set_join_pathlist_hook_type) (PlannerInfo *root,
                                              RelOptInfo *joinrel,
                                              RelOptInfo *outerrel,
                                              RelOptInfo *innerrel,
```

```
                                JoinType jointype,  
                                JoinPathExtraData *extra);  
extern PGDLLIMPORT set_join_pathlist_hook_type set_join_pathlist_hook;
```

This hook will be invoked repeatedly for the same join relation, with different combinations of inner and outer relations; it is the responsibility of the hook to minimize duplicated work.

### 59.1.1. Custom Scan Path Callbacks

```
Plan *(*PlanCustomPath) (PlannerInfo *root,  
                          RelOptInfo *rel,  
                          CustomPath *best_path,  
                          List *tlist,  
                          List *clauses,  
                          List *custom_plans);
```

Convert a custom path to a finished plan. The return value will generally be a `CustomScan` object, which the callback must allocate and initialize. See [Section 59.2](#) for more details.

```
List *(*ReparameterizeCustomPathByChild) (PlannerInfo *root,  
                                           List *custom_private,  
                                           RelOptInfo *child_rel);
```

This callback is called while converting a path parameterized by the top-most parent of the given child relation `child_rel` to be parameterized by the child relation. The callback is used to reparameterize any paths or translate any expression nodes saved in the given `custom_private` member of a `CustomPath`. The callback may use `reparameterize_path_by_child`, `adjust_appendrel_attrs` or `adjust_appendrel_attrs_multilevel` as required.

## 59.2. Creating Custom Scan Plans

A custom scan is represented in a finished plan tree using the following structure:

```
typedef struct CustomScan  
{  
    Scan      scan;  
    uint32    flags;  
    List      *custom_plans;  
    List      *custom_exprs;  
    List      *custom_private;  
    List      *custom_scan_tlist;  
    Bitmapset *custom_relids;  
    const CustomScanMethods *methods;  
} CustomScan;
```

`scan` must be initialized as for any other scan, including estimated costs, target lists, qualifications, and so on. `flags` is a bit mask with the same meaning as in `CustomPath`. `custom_plans` can be used to store child `Plan` nodes. `custom_exprs` should be used to store expression trees that will need to be fixed up by `setrefs.c` and `subselect.c`, while `custom_private` should be used to store other private data that is only used by the custom scan provider itself. `custom_scan_tlist` can be `NIL` when scanning a base relation, indicating that the custom scan returns scan tuples that match the base relation's row type. Otherwise it is a target list describing the actual scan tuples. `custom_scan_tlist` must be provided for joins, and could be provided for scans if the custom scan provider can compute some non-Var expressions. `custom_relids` is set by the core code to the set of relations (range table indexes) that this scan node handles; except when this scan is replacing a join, it will have only one member. `methods` must point to a (usually statically allocated) object implementing the required custom scan methods, which are further detailed below.

When a `CustomScan` scans a single relation, `scan.scanrelid` must be the range table index of the table to be scanned. When it replaces a join, `scan.scanrelid` should be zero.

Plan trees must be able to be duplicated using `copyObject`, so all the data stored within the “custom” fields must consist of nodes that that function can handle. Furthermore, custom scan providers cannot substitute a larger structure that embeds a `CustomScan` for the structure itself, as would be possible for a `CustomPath` or `CustomScanState`.

### 59.2.1. Custom Scan Plan Callbacks

```
Node *(*CreateCustomScanState) (CustomScan *cscan);
```

Allocate a `CustomScanState` for this `CustomScan`. The actual allocation will often be larger than required for an ordinary `CustomScanState`, because many providers will wish to embed that as the first field of a larger structure. The value returned must have the node tag and methods set appropriately, but other fields should be left as zeroes at this stage; after `ExecInitCustomScan` performs basic initialization, the `BeginCustomScan` callback will be invoked to give the custom scan provider a chance to do whatever else is needed.

## 59.3. Executing Custom Scans

When a `CustomScan` is executed, its execution state is represented by a `CustomScanState`, which is declared as follows:

```
typedef struct CustomScanState
{
    ScanState ss;
    uint32    flags;
    const CustomExecMethods *methods;
} CustomScanState;
```

`ss` is initialized as for any other scan state, except that if the scan is for a join rather than a base relation, `ss.ss_currentRelation` is left `NULL`. `flags` is a bit mask with the same meaning as in `CustomPath` and `CustomScan`. `methods` must point to a (usually statically allocated) object implementing the required custom scan state methods, which are further detailed below. Typically, a `CustomScanState`, which need not support `copyObject`, will actually be a larger structure embedding the above as its first member.

### 59.3.1. Custom Scan Execution Callbacks

```
void (*BeginCustomScan) (CustomScanState *node,
                        EState *estate,
                        int eflags);
```

Complete initialization of the supplied `CustomScanState`. Standard fields have been initialized by `ExecInitCustomScan`, but any private fields should be initialized here.

```
TupleTableSlot *(*ExecCustomScan) (CustomScanState *node);
```

Fetch the next scan tuple. If any tuples remain, it should fill `ps_ResultTupleSlot` with the next tuple in the current scan direction, and then return the tuple slot. If not, `NULL` or an empty slot should be returned.

```
void (*EndCustomScan) (CustomScanState *node);
```

Clean up any private data associated with the `CustomScanState`. This method is required, but it does not need to do anything if there is no associated data or it will be cleaned up automatically.

```
void (*ReScanCustomScan) (CustomScanState *node);
```

Rewind the current scan to the beginning and prepare to rescan the relation.

```
void (*MarkPosCustomScan) (CustomScanState *node);
```

Save the current scan position so that it can subsequently be restored by the `RestrPosCustomScan` callback. This callback is optional, and need only be supplied if the `CUSTOMPATH_SUPPORT_MARK_RESTORE` flag is set.

```
void (*RestrPosCustomScan) (CustomScanState *node);
```

Restore the previous scan position as saved by the `MarkPosCustomScan` callback. This callback is optional, and need only be supplied if the `CUSTOMPATH_SUPPORT_MARK_RESTORE` flag is set.

```
Size (*EstimateDSMCustomScan) (CustomScanState *node,
                               ParallelContext *pcxt);
```

Estimate the amount of dynamic shared memory that will be required for parallel operation. This may be higher than the amount that will actually be used, but it must not be lower. The return value is in bytes. This callback is optional, and need only be supplied if this custom scan provider supports parallel execution.

```
void (*InitializeDSMCustomScan) (CustomScanState *node,
                                ParallelContext *pcxt,
                                void *coordinate);
```

Initialize the dynamic shared memory that will be required for parallel operation. `coordinate` points to a shared memory area of size equal to the return value of `EstimateDSMCustomScan`. This callback is optional, and need only be supplied if this custom scan provider supports parallel execution.

```
void (*ReInitializeDSMCustomScan) (CustomScanState *node,
                                   ParallelContext *pcxt,
                                   void *coordinate);
```

Re-initialize the dynamic shared memory required for parallel operation when the custom-scan plan node is about to be re-scanned. This callback is optional, and need only be supplied if this custom scan provider supports parallel execution. Recommended practice is that this callback reset only shared state, while the `ReScanCustomScan` callback resets only local state. Currently, this callback will be called before `ReScanCustomScan`, but it's best not to rely on that ordering.

```
void (*InitializeWorkerCustomScan) (CustomScanState *node,
                                    shm_toc *toc,
                                    void *coordinate);
```

Initialize a parallel worker's local state based on the shared state set up by the leader during `InitializeDSMCustomScan`. This callback is optional, and need only be supplied if this custom scan provider supports parallel execution.

```
void (*ShutdownCustomScan) (CustomScanState *node);
```

Release resources when it is anticipated the node will not be executed to completion. This is not called in all cases; sometimes, `EndCustomScan` may be called without this function having been called first. Since the DSM segment used by parallel query is destroyed just after this callback is invoked, custom scan providers that wish to take some action before the DSM segment goes away should implement this method.

```
void (*ExplainCustomScan) (CustomScanState *node,
                           List *ancestors,
                           ExplainState *es);
```

Output additional information for `EXPLAIN` of a custom-scan plan node. This callback is optional. Common data stored in the `ScanState`, such as the target list and scan relation, will be shown even without this callback, but the callback allows the display of additional, private state.

---

# Chapter 60. Genetic Query Optimizer

## Author

Written by Martin Utesch (<utesch@aut.tu-freiberg.de>) for the Institute of Automatic Control at the University of Mining and Technology in Freiberg, Germany.

## 60.1. Query Handling as a Complex Optimization Problem

Among all relational operators the most difficult one to process and optimize is the *join*. The number of possible query plans grows exponentially with the number of joins in the query. Further optimization effort is caused by the support of a variety of *join methods* (e.g., nested loop, hash join, merge join in Postgres Pro) to process individual joins and a diversity of *indexes* (e.g., B-tree, hash, GiST and GIN in Postgres Pro) as access paths for relations.

The normal Postgres Pro query optimizer performs a *near-exhaustive search* over the space of alternative strategies. This algorithm, first introduced in IBM's System R database, produces a near-optimal join order, but can take an enormous amount of time and memory space when the number of joins in the query grows large. This makes the ordinary Postgres Pro query optimizer inappropriate for queries that join a large number of tables.

The Institute of Automatic Control at the University of Mining and Technology, in Freiberg, Germany, encountered some problems when it wanted to use PostgreSQL as the backend for a decision support knowledge based system for the maintenance of an electrical power grid. The DBMS needed to handle large join queries for the inference machine of the knowledge based system. The number of joins in these queries made using the normal query optimizer infeasible.

In the following we describe the implementation of a *genetic algorithm* to solve the join ordering problem in a manner that is efficient for queries involving large numbers of joins.

## 60.2. Genetic Algorithms

The genetic algorithm (GA) is a heuristic optimization method which operates through randomized search. The set of possible solutions for the optimization problem is considered as a *population of individuals*. The degree of adaptation of an individual to its environment is specified by its *fitness*.

The coordinates of an individual in the search space are represented by *chromosomes*, in essence a set of character strings. A *gene* is a subsection of a chromosome which encodes the value of a single parameter being optimized. Typical encodings for a gene could be *binary* or *integer*.

Through simulation of the evolutionary operations *recombination*, *mutation*, and *selection* new generations of search points are found that show a higher average fitness than their ancestors. [Figure 60.1](#) illustrates these steps.

**Figure 60.1. Structure of a Genetic Algorithm**

According to the comp.ai.genetic FAQ it cannot be stressed too strongly that a GA is not a pure random search for a solution to a problem. A GA uses stochastic processes, but the result is distinctly non-random (better than random).

### 60.3. Genetic Query Optimization (GEQO) in Postgres Pro

The GEQO module approaches the query optimization problem as though it were the well-known traveling salesman problem (TSP). Possible query plans are encoded as integer strings. Each string represents the join order from one relation of the query to the next. For example, the join tree

```

  /\
 /\ 2
 /\ 3

```

4 1

is encoded by the integer string '4-1-3-2', which means, first join relation '4' and '1', then '3', and then '2', where 1, 2, 3, 4 are relation IDs within the Postgres Pro optimizer.

Specific characteristics of the GEQO implementation in Postgres Pro are:

- Usage of a *steady state* GA (replacement of the least fit individuals in a population, not whole-generational replacement) allows fast convergence towards improved query plans. This is essential for query handling with reasonable time;
- Usage of *edge recombination crossover* which is especially suited to keep edge losses low for the solution of the TSP by means of a GA;
- Mutation as genetic operator is deprecated so that no repair mechanisms are needed to generate legal TSP tours.

Parts of the GEQO module are adapted from D. Whitley's Genitor algorithm.

The GEQO module allows the Postgres Pro query optimizer to support large join queries effectively through non-exhaustive search.

### 60.3.1. Generating Possible Plans with GEQO

The GEQO planning process uses the standard planner code to generate plans for scans of individual relations. Then join plans are developed using the genetic approach. As shown above, each candidate join plan is represented by a sequence in which to join the base relations. In the initial stage, the GEQO code simply generates some possible join sequences at random. For each join sequence considered, the standard planner code is invoked to estimate the cost of performing the query using that join sequence. (For each step of the join sequence, all three possible join strategies are considered; and all the initially-determined relation scan plans are available. The estimated cost is the cheapest of these possibilities.) Join sequences with lower estimated cost are considered “more fit” than those with higher cost. The genetic algorithm discards the least fit candidates. Then new candidates are generated by combining genes of more-fit candidates — that is, by using randomly-chosen portions of known low-cost join sequences to create new sequences for consideration. This process is repeated until a preset number of join sequences have been considered; then the best one found at any time during the search is used to generate the finished plan.

This process is inherently nondeterministic, because of the randomized choices made during both the initial population selection and subsequent “mutation” of the best candidates. To avoid surprising changes of the selected plan, each run of the GEQO algorithm restarts its random number generator with the current `geqo_seed` parameter setting. As long as `geqo_seed` and the other GEQO parameters are kept fixed, the same plan will be generated for a given query (and other planner inputs such as statistics). To experiment with different search paths, try changing `geqo_seed`.

### 60.3.2. Future Implementation Tasks for PostgreSQL GEQO

Work is still needed to improve the genetic algorithm parameter settings. We have to find a compromise for the parameter settings to satisfy two competing demands:

- Optimality of the query plan
- Computing time

In the current implementation, the fitness of each candidate join sequence is estimated by running the standard planner's join selection and cost estimation code from scratch. To the extent that different candidates use similar sub-sequences of joins, a great deal of work will be repeated. This could be made significantly faster by retaining cost estimates for sub-joins. The problem is to avoid expending unreasonable amounts of memory on retaining that state.

At a more basic level, it is not clear that solving query optimization with a GA algorithm designed for TSP is appropriate. In the TSP case, the cost associated with any substring (partial tour) is independent of the rest of the tour, but this is certainly not true for query optimization. Thus it is questionable whether edge recombination crossover is the most effective mutation procedure.

# Chapter 61. Table Access Method Interface Definition

This chapter explains the interface between the core PostgreSQL system and *table access methods*, which manage the storage for tables. The core system knows little about these access methods beyond what is specified here, so it is possible to develop entirely new access method types by writing add-on code.

Each table access method is described by a row in the `pg_am` system catalog. The `pg_am` entry specifies a name and a *handler function* for the table access method. These entries can be created and deleted using the `CREATE ACCESS METHOD` and `DROP ACCESS METHOD` SQL commands.

A table access method handler function must be declared to accept a single argument of type `internal` and to return the pseudo-type `table_am_handler`. The argument is a dummy value that simply serves to prevent handler functions from being called directly from SQL commands. The result of the function must be a pointer to a struct of type `TableAmRoutine`, which contains everything that the core code needs to know to make use of the table access method. The return value needs to be of server lifetime, which is typically achieved by defining it as a `static const` variable in global scope. The `TableAmRoutine` struct, also called the access method's *API struct*, defines the behavior of the access method using callbacks. These callbacks are pointers to plain C functions and are not visible or callable at the SQL level. All the callbacks and their behavior is defined in the `TableAmRoutine` structure (with comments inside the struct defining the requirements for callbacks). Most callbacks have wrapper functions, which are documented from the point of view of a user (rather than an implementor) of the table access method. For details, please refer to the `src/include/access/tableam.h` file.

To implement an access method, an implementor will typically need to implement an AM-specific type of tuple table slot (see `src/include/executor/tuptable.h`), which allows code outside the access method to hold references to tuples of the AM, and to access the columns of the tuple.

Currently, the way an AM actually stores data is fairly unconstrained. For example, it's possible, but not required, to use postgres' shared buffer cache. In case it is used, it likely makes sense to use PostgreSQL's standard page layout as described in [Section 70.6](#).

One fairly large constraint of the table access method API is that, currently, if the AM wants to support modifications and/or indexes, it is necessary for each tuple to have a tuple identifier (TID) consisting of a block number and an item number (see also [Section 70.6](#)). It is not strictly necessary that the sub-parts of TIDs have the same meaning they e.g., have for `heap`, but if bitmap scan support is desired (it is optional), the block number needs to provide locality.

For crash safety, an AM can use postgres' [WAL](#), or a custom implementation. If WAL is chosen, either [Generic WAL Records](#) can be used, or a new type of WAL records can be implemented. Generic WAL Records are easy, but imply higher WAL volume. Implementation of a new type of WAL record currently requires modifications to core code (specifically, `src/include/access/rmgrlist.h`).

To implement transactional support in a manner that allows different table access methods be accessed within a single transaction, it likely is necessary to closely integrate with the machinery in `src/backend/access/transam/xlog.c`.

---

# Chapter 62. Index Access Method Interface Definition

This chapter defines the interface between the core Postgres Pro system and *index access methods*, which manage individual index types. The core system knows nothing about indexes beyond what is specified here, so it is possible to develop entirely new index types by writing add-on code.

All indexes in Postgres Pro are what are known technically as *secondary indexes*; that is, the index is physically separate from the table file that it describes. Each index is stored as its own physical *relation* and so is described by an entry in the `pg_class` catalog. The contents of an index are entirely under the control of its index access method. In practice, all index access methods divide indexes into standard-size pages so that they can use the regular storage manager and buffer manager to access the index contents. (All the existing index access methods furthermore use the standard page layout described in [Section 70.6](#), and most use the same format for index tuple headers; but these decisions are not forced on an access method.)

An index is effectively a mapping from some data key values to *tuple identifiers*, or TIDs, of row versions (tuples) in the index's parent table. A TID consists of a block number and an item number within that block (see [Section 70.6](#)). This is sufficient information to fetch a particular row version from the table. Indexes are not directly aware that under MVCC, there might be multiple extant versions of the same logical row; to an index, each tuple is an independent object that needs its own index entry. Thus, an update of a row always creates all-new index entries for the row, even if the key values did not change. ([HOT tuples](#) are an exception to this statement; but indexes do not deal with those, either.) Index entries for dead tuples are reclaimed (by vacuuming) when the dead tuples themselves are reclaimed.

## 62.1. Basic API Structure for Indexes

Each index access method is described by a row in the `pg_am` system catalog. The `pg_am` entry specifies a name and a *handler function* for the index access method. These entries can be created and deleted using the [CREATE ACCESS METHOD](#) and [DROP ACCESS METHOD](#) SQL commands.

An index access method handler function must be declared to accept a single argument of type `internal` and to return the pseudo-type `index_am_handler`. The argument is a dummy value that simply serves to prevent handler functions from being called directly from SQL commands. The result of the function must be a palloc'd struct of type `IndexAmRoutine`, which contains everything that the core code needs to know to make use of the index access method. The `IndexAmRoutine` struct, also called the access method's *API struct*, includes fields specifying assorted fixed properties of the access method, such as whether it can support multicolumn indexes. More importantly, it contains pointers to support functions for the access method, which do all of the real work to access indexes. These support functions are plain C functions and are not visible or callable at the SQL level. The support functions are described in [Section 62.2](#).

The structure `IndexAmRoutine` is defined thus:

```
typedef struct IndexAmRoutine
{
    NodeTag      type;

    /*
     * Total number of strategies (operators) by which we can traverse/search
     * this AM. Zero if AM does not have a fixed set of strategy assignments.
     */
    uint16       amstrategies;
    /* total number of support functions that this AM uses */
    uint16       amsupport;
    /* opclass options support function number or 0 */
    uint16       amoptsprocnum;
    /* does AM support ORDER BY indexed column's value? */

```

## Index Access Method Interface Definition

---

```
bool            amcanorder;
/* does AM support ORDER BY result of an operator on indexed column? */
bool            amcanorderbyop;
/*
 * Does AM support only one ORDER BY operator on first indexed column?
 * amcanorderbyop is implied.
 */
bool            amorderbyopfirstcol;
/* does AM support backward scanning? */
bool            amcanbackward;
/* does AM support UNIQUE indexes? */
bool            amcanunique;
/* does AM support multi-column indexes? */
bool            amcanmulticol;
/* does AM require scans to have a constraint on the first index column? */
bool            amoptionalkey;
/* does AM handle ScalarArrayOpExpr quals? */
bool            amsearcharray;
/* does AM handle IS NULL/IS NOT NULL quals? */
bool            amsearchnulls;
/* can index storage data type differ from column data type? */
bool            amstorage;
/* can an index of this type be clustered on? */
bool            amclusterable;
/* does AM handle predicate locks? */
bool            ampredlocks;
/* does AM support parallel scan? */
bool            amcanparallel;
/* does AM support columns included with clause INCLUDE? */
bool            amcaninclude;
/* does AM use maintenance_work_mem? */
bool            amusemaintenanceworkmem;
/* OR of parallel vacuum flags */
uint8           amparallelvacuumoptions;
/* type of data stored in index, or InvalidOid if variable */
Oid             amkeytype;

/* interface functions */
ambuild_function ambuild;
ambuildempty_function ambuildempty;
aminert_function aminert;
ambulkdelete_function ambulkdelete;
amvacuumcleanup_function amvacuumcleanup;
amcanreturn_function amcanreturn; /* can be NULL */
amcostestimate_function amcostestimate;
amoptions_function amoptions;
amproperty_function amproperty; /* can be NULL */
ambuildphasename_function ambuildphasename; /* can be NULL */
amvalidate_function amvalidate;
amadjustmembers_function amadjustmembers; /* can be NULL */
ambeginscan_function ambeginscan;
amrescan_function amrescan;
amgettupple_function amgettupple; /* can be NULL */
amgetbitmap_function amgetbitmap; /* can be NULL */
amendscan_function amendscan;
ammarkpos_function ammarkpos; /* can be NULL */
amrestrpos_function amrestrpos; /* can be NULL */
```

```

/* interface functions to support parallel index scans */
amestimateparallelscan_function amestimateparallelscan;    /* can be NULL */
aminitialparallelscan_function aminitialparallelscan;      /* can be NULL */
amparallelrescan_function amparallelrescan;                /* can be NULL */
} IndexAmRoutine;

```

To be useful, an index access method must also have one or more *operator families* and *operator classes* defined in `pg_opfamily`, `pg_opclass`, `pg_amop`, and `pg_amproc`. These entries allow the planner to determine what kinds of query qualifications can be used with indexes of this access method. Operator families and classes are described in [Section 40.16](#), which is prerequisite material for reading this chapter.

An individual index is defined by a `pg_class` entry that describes it as a physical relation, plus a `pg_index` entry that shows the logical content of the index — that is, the set of index columns it has and the semantics of those columns, as captured by the associated operator classes. The index columns (key values) can be either simple columns of the underlying table or expressions over the table rows. The index access method normally has no interest in where the index key values come from (it is always handed precomputed key values) but it will be very interested in the operator class information in `pg_index`. Both of these catalog entries can be accessed as part of the `Relation` data structure that is passed to all operations on the index.

Some of the flag fields of `IndexAmRoutine` have nonobvious implications. The requirements of `amcanunique` are discussed in [Section 62.5](#). The `amcanmulticol` flag asserts that the access method supports multi-key-column indexes, while `amoptionalkey` asserts that it allows scans where no indexable restriction clause is given for the first index column. When `amcanmulticol` is false, `amoptionalkey` essentially says whether the access method supports full-index scans without any restriction clause. Access methods that support multiple index columns *must* support scans that omit restrictions on any or all of the columns after the first; however they are permitted to require some restriction to appear for the first index column, and this is signaled by setting `amoptionalkey` false. One reason that an index AM might set `amoptionalkey` false is if it doesn't index null values. Since most indexable operators are strict and hence cannot return true for null inputs, it is at first sight attractive to not store index entries for null values: they could never be returned by an index scan anyway. However, this argument fails when an index scan has no restriction clause for a given index column. In practice this means that indexes that have `amoptionalkey` true must index nulls, since the planner might decide to use such an index with no scan keys at all. A related restriction is that an index access method that supports multiple index columns *must* support indexing null values in columns after the first, because the planner will assume the index can be used for queries that do not restrict these columns. For example, consider an index on (a,b) and a query with `WHERE a = 4`. The system will assume the index can be used to scan for rows with `a = 4`, which is wrong if the index omits rows where `b` is null. It is, however, OK to omit rows where the first indexed column is null. An index access method that does index nulls may also set `amsearchnulls`, indicating that it supports `IS NULL` and `IS NOT NULL` clauses as search conditions.

The `amcaninclude` flag indicates whether the access method supports “included” columns, that is it can store (without processing) additional columns beyond the key column(s). The requirements of the preceding paragraph apply only to the key columns. In particular, the combination of `amcanmulticol=false` and `amcaninclude=true` is sensible: it means that there can only be one key column, but there can also be included column(s). Also, included columns must be allowed to be null, independently of `amoptionalkey`.

## 62.2. Index Access Method Functions

The index construction and maintenance functions that an index access method must provide in `IndexAmRoutine` are:

```

IndexBuildResult *
ambuild (Relation heapRelation,
         Relation indexRelation,
         IndexInfo *indexInfo);

```

Build a new index. The index relation has been physically created, but is empty. It must be filled in with whatever fixed data the access method requires, plus entries for all tuples already existing in the table.

Ordinarily the `ambuild` function will call `table_index_build_scan()` to scan the table for existing tuples and compute the keys that need to be inserted into the index. The function must return a palloc'd struct containing statistics about the new index.

```
void
ambuildempty (Relation indexRelation);
```

Build an empty index, and write it to the initialization fork (`INIT_FORKNUM`) of the given relation. This method is called only for unlogged indexes; the empty index written to the initialization fork will be copied over the main relation fork on each server restart.

```
bool
aminert (Relation indexRelation,
        Datum *values,
        bool *isnull,
        ItemPointer heap_tid,
        Relation heapRelation,
        IndexUniqueCheck checkUnique,
        bool indexUnchanged,
        IndexInfo *indexInfo);
```

Insert a new tuple into an existing index. The `values` and `isnull` arrays give the key values to be indexed, and `heap_tid` is the TID to be indexed. If the access method supports unique indexes (its `amcanunique` flag is true) then `checkUnique` indicates the type of uniqueness check to perform. This varies depending on whether the unique constraint is deferrable; see [Section 62.5](#) for details. Normally the access method only needs the `heapRelation` parameter when performing uniqueness checking (since then it will have to look into the heap to verify tuple liveness).

The `indexUnchanged` Boolean value gives a hint about the nature of the tuple to be indexed. When it is true, the tuple is a duplicate of some existing tuple in the index. The new tuple is a logically unchanged successor MVCC tuple version. This happens when an `UPDATE` takes place that does not modify any columns covered by the index, but nevertheless requires a new version in the index. The index AM may use this hint to decide to apply bottom-up index deletion in parts of the index where many versions of the same logical row accumulate. Note that updating a non-key column or a column that only appears in a partial index predicate does not affect the value of `indexUnchanged`. The core code determines each tuple's `indexUnchanged` value using a low overhead approach that allows both false positives and false negatives. Index AMs must not treat `indexUnchanged` as an authoritative source of information about tuple visibility or versioning.

The function's Boolean result value is significant only when `checkUnique` is `UNIQUE_CHECK_PARTIAL`. In this case a true result means the new entry is known unique, whereas false means it might be non-unique (and a deferred uniqueness check must be scheduled). For other cases a constant false result is recommended.

Some indexes might not index all tuples. If the tuple is not to be indexed, `aminert` should just return without doing anything.

If the index AM wishes to cache data across successive index insertions within an SQL statement, it can allocate space in `indexInfo->ii_Context` and store a pointer to the data in `indexInfo->ii_AmCache` (which will be NULL initially).

```
IndexBulkDeleteResult *
ambulkdelete (IndexVacuumInfo *info,
             IndexBulkDeleteResult *stats,
             IndexBulkDeleteCallback callback,
             void *callback_state);
```

Delete tuple(s) from the index. This is a “bulk delete” operation that is intended to be implemented by scanning the whole index and checking each entry to see if it should be deleted. The passed-in `callback` function must be called, in the style `callback(TID, callback_state)` returns `bool`, to determine whether any particular index entry, as identified by its referenced TID, is to be deleted. Must return

either NULL or a palloc'd struct containing statistics about the effects of the deletion operation. It is OK to return NULL if no information needs to be passed on to `amvacuumcleanup`.

Because of limited `maintenance_work_mem`, `ambulkdelete` might need to be called more than once when many tuples are to be deleted. The `stats` argument is the result of the previous call for this index (it is NULL for the first call within a `VACUUM` operation). This allows the AM to accumulate statistics across the whole operation. Typically, `ambulkdelete` will modify and return the same struct if the passed `stats` is not null.

```
IndexBulkDeleteResult *
amvacuumcleanup (IndexVacuumInfo *info,
                 IndexBulkDeleteResult *stats);
```

Clean up after a `VACUUM` operation (zero or more `ambulkdelete` calls). This does not have to do anything beyond returning index statistics, but it might perform bulk cleanup such as reclaiming empty index pages. `stats` is whatever the last `ambulkdelete` call returned, or NULL if `ambulkdelete` was not called because no tuples needed to be deleted. If the result is not NULL it must be a palloc'd struct. The statistics it contains will be used to update `pg_class`, and will be reported by `VACUUM` if `VERBOSE` is given. It is OK to return NULL if the index was not changed at all during the `VACUUM` operation, but otherwise correct stats should be returned.

`amvacuumcleanup` will also be called at completion of an `ANALYZE` operation. In this case `stats` is always NULL and any return value will be ignored. This case can be distinguished by checking `info->analyze_only`. It is recommended that the access method do nothing except post-insert cleanup in such a call, and that only in an autovacuum worker process.

```
bool
amcanreturn (Relation indexRelation, int attno);
```

Check whether the index can support *index-only scans* on the given column, by returning the column's original indexed value. The attribute number is 1-based, i.e., the first column's `attno` is 1. Returns true if supported, else false. This function should always return true for included columns (if those are supported), since there's little point in an included column that can't be retrieved. If the access method does not support index-only scans at all, the `amcanreturn` field in its `IndexAmRoutine` struct can be set to NULL.

```
void
amcostestimate (PlannerInfo *root,
                IndexPath *path,
                double loop_count,
                Cost *indexStartupCost,
                Cost *indexTotalCost,
                Selectivity *indexSelectivity,
                double *indexCorrelation,
                double *indexPages);
```

Estimate the costs of an index scan. This function is described fully in [Section 62.6](#), below.

```
bytea *
amoptions (ArrayType *reloptions,
           bool validate);
```

Parse and validate the reloptions array for an index. This is called only when a non-null reloptions array exists for the index. `reloptions` is a text array containing entries of the form `name=value`. The function should construct a `bytea` value, which will be copied into the `rd_options` field of the index's relcache entry. The data contents of the `bytea` value are open for the access method to define; most of the standard access methods use struct `StdRdOptions`. When `validate` is true, the function should report a suitable error message if any of the options are unrecognized or have invalid values; when `validate` is false, invalid entries should be silently ignored. (`validate` is false when loading options already stored in `pg_catalog`; an invalid entry could only be found if the access method has changed its rules for options, and in that case ignoring obsolete entries is appropriate.) It is OK to return NULL if default behavior is wanted.

```
bool
amproperty (Oid index_oid, int attno,
            IndexAMProperty prop, const char *propname,
            bool *res, bool *isnull);
```

The `amproperty` method allows index access methods to override the default behavior of `pg_index_column_has_property` and related functions. If the access method does not have any special behavior for index property inquiries, the `amproperty` field in its `IndexAmRoutine` struct can be set to `NULL`. Otherwise, the `amproperty` method will be called with `index_oid` and `attno` both zero for `pg_indexam_has_property` calls, or with `index_oid` valid and `attno` zero for `pg_index_has_property` calls, or with `index_oid` valid and `attno` greater than zero for `pg_index_column_has_property` calls. `prop` is an enum value identifying the property being tested, while `propname` is the original property name string. If the core code does not recognize the property name then `prop` is `AMPROP_UNKNOWN`. Access methods can define custom property names by checking `propname` for a match (use `pg_strcasecmp` to match, for consistency with the core code); for names known to the core code, it's better to inspect `prop`. If the `amproperty` method returns `true` then it has determined the property test result: it must set `*res` to the Boolean value to return, or set `*isnull` to `true` to return a `NULL`. (Both of the referenced variables are initialized to `false` before the call.) If the `amproperty` method returns `false` then the core code will proceed with its normal logic for determining the property test result.

Access methods that support ordering operators should implement `AMPROP_DISTANCE_ORDERABLE` property testing, as the core code does not know how to do that and will return `NULL`. It may also be advantageous to implement `AMPROP_RETURNABLE` testing, if that can be done more cheaply than by opening the index and calling `amcanreturn`, which is the core code's default behavior. The default behavior should be satisfactory for all other standard properties.

```
char *
ambuildphasename (int64 phasenum);
```

Return the textual name of the given build phase number. The phase numbers are those reported during an index build via the `pgstat_progress_update_param` interface. The phase names are then exposed in the `pg_stat_progress_create_index` view.

```
bool
amvalidate (Oid opclassoid);
```

Validate the catalog entries for the specified operator class, so far as the access method can reasonably do that. For example, this might include testing that all required support functions are provided. The `amvalidate` function must return `false` if the `opclass` is invalid. Problems should be reported with `ereport` messages, typically at `INFO` level.

```
void
amadjustmembers (Oid opfamilyoid,
                 Oid opclassoid,
                 List *operators,
                 List *functions);
```

Validate proposed new operator and function members of an operator family, so far as the access method can reasonably do that, and set their dependency types if the default is not satisfactory. This is called during `CREATE OPERATOR CLASS` and during `ALTER OPERATOR FAMILY ADD`; in the latter case `opclassoid` is `InvalidOid`. The `List` arguments are lists of `OpFamilyMember` structs. Tests done by this function will typically be a subset of those performed by `amvalidate`, since `amadjustmembers` cannot assume that it is seeing a complete set of members. For example, it would be reasonable to check the signature of a support function, but not to check whether all required support functions are provided. Any problems can be reported by throwing an error. The dependency-related fields of the `OpFamilyMember` structs are initialized by the core code to create hard dependencies on the `opclass` if this is `CREATE OPERATOR CLASS`, or soft dependencies on the `opfamily` if this is `ALTER OPERATOR FAMILY ADD`. `amadjustmembers` can adjust these fields if some other behavior is more appropriate. For example, `GIN`, `GiST`, and `SP-GiST` always set operator members to have soft dependencies on the `opfamily`, since the connection between an operator and an `opclass` is relatively weak in these index types; so it is reasonable to allow operator members to

be added and removed freely. Optional support functions are typically also given soft dependencies, so that they can be removed if necessary.

The purpose of an index, of course, is to support scans for tuples matching an indexable `WHERE` condition, often called a *qualifier* or *scan key*. The semantics of index scanning are described more fully in [Section 62.3](#), below. An index access method can support “plain” index scans, “bitmap” index scans, or both. The scan-related functions that an index access method must or may provide are:

```
IndexScanDesc
ambeginscan (Relation indexRelation,
             int nkeys,
             int norderbys);
```

Prepare for an index scan. The `nkeys` and `norderbys` parameters indicate the number of quals and ordering operators that will be used in the scan; these may be useful for space allocation purposes. Note that the actual values of the scan keys aren't provided yet. The result must be a palloc'd struct. For implementation reasons the index access method *must* create this struct by calling `RelationGetIndexScan()`. In most cases `ambeginscan` does little beyond making that call and perhaps acquiring locks; the interesting parts of index-scan startup are in `amrescan`.

```
void
amrescan (IndexScanDesc scan,
          ScanKey keys,
          int nkeys,
          ScanKey orderbys,
          int norderbys);
```

Start or restart an index scan, possibly with new scan keys. (To restart using previously-passed keys, `NULL` is passed for `keys` and/or `orderbys`.) Note that it is not allowed for the number of keys or order-by operators to be larger than what was passed to `ambeginscan`. In practice the restart feature is used when a new outer tuple is selected by a nested-loop join and so a new key comparison value is needed, but the scan key structure remains the same.

```
bool
amgettupple (IndexScanDesc scan,
             ScanDirection direction);
```

Fetch the next tuple in the given scan, moving in the given direction (forward or backward in the index). Returns true if a tuple was obtained, false if no matching tuples remain. In the true case the tuple TID is stored into the `scan` structure. Note that “success” means only that the index contains an entry that matches the scan keys, not that the tuple necessarily still exists in the heap or will pass the caller's snapshot test. On success, `amgettupple` must also set `scan->xs_recheck` to true or false. False means it is certain that the index entry matches the scan keys. True means this is not certain, and the conditions represented by the scan keys must be rechecked against the heap tuple after fetching it. This provision supports “lossy” index operators. Note that rechecking will extend only to the scan conditions; a partial index predicate (if any) is never rechecked by `amgettupple` callers.

If the index supports [index-only scans](#) (i.e., `amcanreturn` returns true for any of its columns), then on success the AM must also check `scan->xs_want_itup`, and if that is true it must return the originally indexed data for the index entry. Columns for which `amcanreturn` returns false can be returned as nulls. The data can be returned in the form of an `IndexTuple` pointer stored at `scan->xs_itup`, with tuple descriptor `scan->xs_itupdesc`; or in the form of a `HeapTuple` pointer stored at `scan->xs_hitup`, with tuple descriptor `scan->xs_hitupdesc`. (The latter format should be used when reconstructing data that might possibly not fit into an `IndexTuple`.) In either case, management of the data referenced by the pointer is the access method's responsibility. The data must remain good at least until the next `amgettupple`, `amrescan`, or `amendscan` call for the scan.

The `amgettupple` function need only be provided if the access method supports “plain” index scans. If it doesn't, the `amgettupple` field in its `IndexAmRoutine` struct must be set to `NULL`.

```
int64
```

```
amgetbitmap (IndexScanDesc scan,
            TIDBitmap *tbm);
```

Fetch all tuples in the given scan and add them to the caller-supplied `TIDBitmap` (that is, OR the set of tuple IDs into whatever set is already in the bitmap). The number of tuples fetched is returned (this might be just an approximate count, for instance some AMs do not detect duplicates). While inserting tuple IDs into the bitmap, `amgetbitmap` can indicate that rechecking of the scan conditions is required for specific tuple IDs. This is analogous to the `xs_recheck` output parameter of `amgettupple`. Note: in the current implementation, support for this feature is conflated with support for lossy storage of the bitmap itself, and therefore callers recheck both the scan conditions and the partial index predicate (if any) for recheckable tuples. That might not always be true, however. `amgetbitmap` and `amgettupple` cannot be used in the same index scan; there are other restrictions too when using `amgetbitmap`, as explained in [Section 62.3](#).

The `amgetbitmap` function need only be provided if the access method supports “bitmap” index scans. If it doesn't, the `amgetbitmap` field in its `IndexAmRoutine` struct must be set to `NULL`.

```
void
amendscan (IndexScanDesc scan);
```

End a scan and release resources. The `scan` struct itself should not be freed, but any locks or pins taken internally by the access method must be released, as well as any other memory allocated by `ambeginscan` and other scan-related functions.

```
void
ammarkpos (IndexScanDesc scan);
```

Mark current scan position. The access method need only support one remembered scan position per scan.

The `ammarkpos` function need only be provided if the access method supports ordered scans. If it doesn't, the `ammarkpos` field in its `IndexAmRoutine` struct may be set to `NULL`.

```
void
amrestrpos (IndexScanDesc scan);
```

Restore the scan to the most recently marked position.

The `amrestrpos` function need only be provided if the access method supports ordered scans. If it doesn't, the `amrestrpos` field in its `IndexAmRoutine` struct may be set to `NULL`.

In addition to supporting ordinary index scans, some types of index may wish to support *parallel index scans*, which allow multiple backends to cooperate in performing an index scan. The index access method should arrange things so that each cooperating process returns a subset of the tuples that would be performed by an ordinary, non-parallel index scan, but in such a way that the union of those subsets is equal to the set of tuples that would be returned by an ordinary, non-parallel index scan. Furthermore, while there need not be any global ordering of tuples returned by a parallel scan, the ordering of that subset of tuples returned within each cooperating backend must match the requested ordering. The following functions may be implemented to support parallel index scans:

```
Size
amestimateparallelscale (void);
```

Estimate and return the number of bytes of dynamic shared memory which the access method will be needed to perform a parallel scan. (This number is in addition to, not in lieu of, the amount of space needed for AM-independent data in `ParallelIndexScanDescData`.)

It is not necessary to implement this function for access methods which do not support parallel scans or for which the number of additional bytes of storage required is zero.

```
void
aminitparallelscale (void *target);
```

This function will be called to initialize dynamic shared memory at the beginning of a parallel scan. *target* will point to at least the number of bytes previously returned by `amestimateparallelscore`, and this function may use that amount of space to store whatever data it wishes.

It is not necessary to implement this function for access methods which do not support parallel scans or in cases where the shared memory space required needs no initialization.

```
void  
amparallelrescan (IndexScanDesc scan);
```

This function, if implemented, will be called when a parallel index scan must be restarted. It should reset any shared state set up by `aminitparallelscore` such that the scan will be restarted from the beginning.

## 62.3. Index Scanning

In an index scan, the index access method is responsible for regurgitating the TIDs of all the tuples it has been told about that match the *scan keys*. The access method is *not* involved in actually fetching those tuples from the index's parent table, nor in determining whether they pass the scan's visibility test or other conditions.

A scan key is the internal representation of a `WHERE` clause of the form *index\_key operator constant*, where the index key is one of the columns of the index and the operator is one of the members of the operator family associated with that index column. An index scan has zero or more scan keys, which are implicitly ANDed — the returned tuples are expected to satisfy all the indicated conditions.

The access method can report that the index is *lossy*, or requires rechecks, for a particular query. This implies that the index scan will return all the entries that pass the scan key, plus possibly additional entries that do not. The core system's index-scan machinery will then apply the index conditions again to the heap tuple to verify whether or not it really should be selected. If the recheck option is not specified, the index scan must return exactly the set of matching entries.

Note that it is entirely up to the access method to ensure that it correctly finds all and only the entries passing all the given scan keys. Also, the core system will simply hand off all the `WHERE` clauses that match the index keys and operator families, without any semantic analysis to determine whether they are redundant or contradictory. As an example, given `WHERE x > 4 AND x > 14` where *x* is a b-tree indexed column, it is left to the b-tree `amrescan` function to realize that the first scan key is redundant and can be discarded. The extent of preprocessing needed during `amrescan` will depend on the extent to which the index access method needs to reduce the scan keys to a “normalized” form.

Some access methods return index entries in a well-defined order, others do not. There are actually two different ways that an access method can support sorted output:

- Access methods that always return entries in the natural ordering of their data (such as btree) should set `amcanorder` to true. Currently, such access methods must use btree-compatible strategy numbers for their equality and ordering operators.
- Access methods that support ordering operators should set `amcanorderbyop` to true. This indicates that the index is capable of returning entries in an order satisfying `ORDER BY index_key operator constant`. Scan modifiers of that form can be passed to `amrescan` as described previously. If the access method supports only one `ORDER BY` operator on the first indexed column, then it should set `amorderbyopfirstcol` to true.

The `amgettupple` function has a *direction* argument, which can be either `ForwardScanDirection` (the normal case) or `BackwardScanDirection`. If the first call after `amrescan` specifies `BackwardScanDirection`, then the set of matching index entries is to be scanned back-to-front rather than in the normal front-to-back direction, so `amgettupple` must return the last matching tuple in the index, rather than the first one as it normally would. (This will only occur for access methods that set `amcanorder` to true.) After the first call, `amgettupple` must be prepared to advance the scan in either direction from the most recently returned entry. (But if `amcanbackward` is false, all subsequent calls will have the same direction as the first one.)

Access methods that support ordered scans must support “marking” a position in a scan and later returning to the marked position. The same position might be restored multiple times. However, only one position need be remembered per scan; a new `ammarkpos` call overrides the previously marked position. An access method that does not support ordered scans need not provide `ammarkpos` and `amrestrpos` functions in `IndexAmRoutine`; set those pointers to `NULL` instead.

Both the scan position and the mark position (if any) must be maintained consistently in the face of concurrent insertions or deletions in the index. It is OK if a freshly-inserted entry is not returned by a scan that would have found the entry if it had existed when the scan started, or for the scan to return such an entry upon rescanning or backing up even though it had not been returned the first time through. Similarly, a concurrent delete might or might not be reflected in the results of a scan. What is important is that insertions or deletions not cause the scan to miss or multiply return entries that were not themselves being inserted or deleted.

If the index stores the original indexed data values (and not some lossy representation of them), it is useful to support [index-only scans](#), in which the index returns the actual data not just the TID of the heap tuple. This will only avoid I/O if the visibility map shows that the TID is on an all-visible page; else the heap tuple must be visited anyway to check MVCC visibility. But that is no concern of the access method's.

Instead of using `amgettupple`, an index scan can be done with `amgetbitmap` to fetch all tuples in one call. This can be noticeably more efficient than `amgettupple` because it allows avoiding lock/unlock cycles within the access method. In principle `amgetbitmap` should have the same effects as repeated `amgettupple` calls, but we impose several restrictions to simplify matters. First of all, `amgetbitmap` returns all tuples at once and marking or restoring scan positions isn't supported. Secondly, the tuples are returned in a bitmap which doesn't have any specific ordering, which is why `amgetbitmap` doesn't take a `direction` argument. (Ordering operators will never be supplied for such a scan, either.) Also, there is no provision for index-only scans with `amgetbitmap`, since there is no way to return the contents of index tuples. Finally, `amgetbitmap` does not guarantee any locking of the returned tuples, with implications spelled out in [Section 62.4](#).

Note that it is permitted for an access method to implement only `amgetbitmap` and not `amgettupple`, or vice versa, if its internal implementation is unsuited to one API or the other.

## 62.4. Index Locking Considerations

Index access methods must handle concurrent updates of the index by multiple processes. The core Postgres Pro system obtains `AccessShareLock` on the index during an index scan, and `RowExclusiveLock` when updating the index (including plain `VACUUM`). Since these lock types do not conflict, the access method is responsible for handling any fine-grained locking it might need. An `ACCESS EXCLUSIVE` lock on the index as a whole will be taken only during index creation, destruction, or `REINDEX (SHARE UPDATE EXCLUSIVE)` is taken instead with `CONCURRENTLY`).

Building an index type that supports concurrent updates usually requires extensive and subtle analysis of the required behavior.

Aside from the index's own internal consistency requirements, concurrent updates create issues about consistency between the parent table (the *heap*) and the index. Because Postgres Pro separates accesses and updates of the heap from those of the index, there are windows in which the index might be inconsistent with the heap. We handle this problem with the following rules:

- A new heap entry is made before making its index entries. (Therefore a concurrent index scan is likely to fail to see the heap entry. This is okay because the index reader would be uninterested in an uncommitted row anyway. But see [Section 62.5](#).)
- When a heap entry is to be deleted (by `VACUUM`), all its index entries must be removed first.
- An index scan must maintain a pin on the index page holding the item last returned by `amgettupple`, and `ambulkdelete` cannot delete entries from pages that are pinned by other backends. The need for this rule is explained below.

Without the third rule, it is possible for an index reader to see an index entry just before it is removed by `VACUUM`, and then to arrive at the corresponding heap entry after that was removed by `VACUUM`. This creates no serious problems if that item number is still unused when the reader reaches it, since an empty item slot will be ignored by `heap_fetch()`. But what if a third backend has already re-used the item slot for something else? When using an MVCC-compliant snapshot, there is no problem because the new occupant of the slot is certain to be too new to pass the snapshot test. However, with a non-MVCC-compliant snapshot (such as `SnapshotAny`), it would be possible to accept and return a row that does not in fact match the scan keys. We could defend against this scenario by requiring the scan keys to be rechecked against the heap row in all cases, but that is too expensive. Instead, we use a pin on an index page as a proxy to indicate that the reader might still be “in flight” from the index entry to the matching heap entry. Making `ambulkdelete` block on such a pin ensures that `VACUUM` cannot delete the heap entry before the reader is done with it. This solution costs little in run time, and adds blocking overhead only in the rare cases where there actually is a conflict.

This solution requires that index scans be “synchronous”: we have to fetch each heap tuple immediately after scanning the corresponding index entry. This is expensive for a number of reasons. An “asynchronous” scan in which we collect many TIDs from the index, and only visit the heap tuples sometime later, requires much less index locking overhead and can allow a more efficient heap access pattern. Per the above analysis, we must use the synchronous approach for non-MVCC-compliant snapshots, but an asynchronous scan is workable for a query using an MVCC snapshot.

In an `amgetbitmap` index scan, the access method does not keep an index pin on any of the returned tuples. Therefore it is only safe to use such scans with MVCC-compliant snapshots.

When the `ampredlocks` flag is not set, any scan using that index access method within a serializable transaction will acquire a nonblocking predicate lock on the full index. This will generate a read-write conflict with the insert of any tuple into that index by a concurrent serializable transaction. If certain patterns of read-write conflicts are detected among a set of concurrent serializable transactions, one of those transactions may be canceled to protect data integrity. When the flag is set, it indicates that the index access method implements finer-grained predicate locking, which will tend to reduce the frequency of such transaction cancellations.

## 62.5. Index Uniqueness Checks

Postgres Pro enforces SQL uniqueness constraints using *unique indexes*, which are indexes that disallow multiple entries with identical keys. An access method that supports this feature sets `amcanunique` true. (At present, only b-tree supports it.) Columns listed in the `INCLUDE` clause are not considered when enforcing uniqueness.

Because of MVCC, it is always necessary to allow duplicate entries to exist physically in an index: the entries might refer to successive versions of a single logical row. The behavior we actually want to enforce is that no MVCC snapshot could include two rows with equal index keys. This breaks down into the following cases that must be checked when inserting a new row into a unique index:

- If a conflicting valid row has been deleted by the current transaction, it's okay. (In particular, since an `UPDATE` always deletes the old row version before inserting the new version, this will allow an `UPDATE` on a row without changing the key.)
- If a conflicting row has been inserted by an as-yet-uncommitted transaction, the would-be inserter must wait to see if that transaction commits. If it rolls back then there is no conflict. If it commits without deleting the conflicting row again, there is a uniqueness violation. (In practice we just wait for the other transaction to end and then redo the visibility check in toto.)
- Similarly, if a conflicting valid row has been deleted by an as-yet-uncommitted transaction, the would-be inserter must wait for that transaction to commit or abort, and then repeat the test.

Furthermore, immediately before reporting a uniqueness violation according to the above rules, the access method must recheck the liveness of the row being inserted. If it is committed dead then no violation should be reported. (This case cannot occur during the ordinary scenario of inserting a row that's just been created by the current transaction. It can happen during `CREATE UNIQUE INDEX CONCURRENTLY`, however.)

We require the index access method to apply these tests itself, which means that it must reach into the heap to check the commit status of any row that is shown to have a duplicate key according to the index contents. This is without a doubt ugly and non-modular, but it saves redundant work: if we did a separate probe then the index lookup for a conflicting row would be essentially repeated while finding the place to insert the new row's index entry. What's more, there is no obvious way to avoid race conditions unless the conflict check is an integral part of insertion of the new index entry.

If the unique constraint is deferrable, there is additional complexity: we need to be able to insert an index entry for a new row, but defer any uniqueness-violation error until end of statement or even later. To avoid unnecessary repeat searches of the index, the index access method should do a preliminary uniqueness check during the initial insertion. If this shows that there is definitely no conflicting live tuple, we are done. Otherwise, we schedule a recheck to occur when it is time to enforce the constraint. If, at the time of the recheck, both the inserted tuple and some other tuple with the same key are live, then the error must be reported. (Note that for this purpose, “live” actually means “any tuple in the index entry's HOT chain is live”.) To implement this, the `aminert` function is passed a `checkUnique` parameter having one of the following values:

- `UNIQUE_CHECK_NO` indicates that no uniqueness checking should be done (this is not a unique index).
- `UNIQUE_CHECK_YES` indicates that this is a non-deferrable unique index, and the uniqueness check must be done immediately, as described above.
- `UNIQUE_CHECK_PARTIAL` indicates that the unique constraint is deferrable. Postgres Pro will use this mode to insert each row's index entry. The access method must allow duplicate entries into the index, and report any potential duplicates by returning false from `aminert`. For each row for which false is returned, a deferred recheck will be scheduled.

The access method must identify any rows which might violate the unique constraint, but it is not an error for it to report false positives. This allows the check to be done without waiting for other transactions to finish; conflicts reported here are not treated as errors and will be rechecked later, by which time they may no longer be conflicts.

- `UNIQUE_CHECK_EXISTING` indicates that this is a deferred recheck of a row that was reported as a potential uniqueness violation. Although this is implemented by calling `aminert`, the access method must *not* insert a new index entry in this case. The index entry is already present. Rather, the access method must check to see if there is another live index entry. If so, and if the target row is also still live, report error.

It is recommended that in a `UNIQUE_CHECK_EXISTING` call, the access method further verify that the target row actually does have an existing entry in the index, and report error if not. This is a good idea because the index tuple values passed to `aminert` will have been recomputed. If the index definition involves functions that are not really immutable, we might be checking the wrong area of the index. Checking that the target row is found in the recheck verifies that we are scanning for the same tuple values as were used in the original insertion.

## 62.6. Index Cost Estimation Functions

The `amcostestimate` function is given information describing a possible index scan, including lists of WHERE and ORDER BY clauses that have been determined to be usable with the index. It must return estimates of the cost of accessing the index and the selectivity of the WHERE clauses (that is, the fraction of parent-table rows that will be retrieved during the index scan). For simple cases, nearly all the work of the cost estimator can be done by calling standard routines in the optimizer; the point of having an `amcostestimate` function is to allow index access methods to provide index-type-specific knowledge, in case it is possible to improve on the standard estimates.

Each `amcostestimate` function must have the signature:

```
void
amcostestimate (PlannerInfo *root,
               IndexPath *path,
```

```
double loop_count,  
Cost *indexStartupCost,  
Cost *indexTotalCost,  
Selectivity *indexSelectivity,  
double *indexCorrelation,  
double *indexPages);
```

The first three parameters are inputs:

*root*

The planner's information about the query being processed.

*path*

The index access path being considered. All fields except cost and selectivity values are valid.

*loop\_count*

The number of repetitions of the index scan that should be factored into the cost estimates. This will typically be greater than one when considering a parameterized scan for use in the inside of a nestloop join. Note that the cost estimates should still be for just one scan; a larger *loop\_count* means that it may be appropriate to allow for some caching effects across multiple scans.

The last five parameters are pass-by-reference outputs:

*\*indexStartupCost*

Set to cost of index start-up processing

*\*indexTotalCost*

Set to total cost of index processing

*\*indexSelectivity*

Set to index selectivity

*\*indexCorrelation*

Set to correlation coefficient between index scan order and underlying table's order

*\*indexPages*

Set to number of index leaf pages

Note that cost estimate functions must be written in C, not in SQL or any available procedural language, because they must access internal data structures of the planner/optimizer.

The index access costs should be computed using the parameters: a sequential disk block fetch has cost *seq\_page\_cost*, a nonsequential fetch has cost *random\_page\_cost*, and the cost of processing one index row should usually be taken as *cpu\_index\_tuple\_cost*. In addition, an appropriate multiple of *cpu\_operator\_cost* should be charged for any comparison operators invoked during index processing (especially evaluation of the *indexquals* themselves).

The “start-up cost” is the part of the total scan cost that must be expended before we can begin to fetch the first row. For most indexes this can be taken as zero, but an index type with a high start-up cost might want to set it nonzero.

The *indexSelectivity* should be set to the estimated fraction of the parent table rows that will be retrieved during the index scan. In the case of a lossy query, this will typically be higher than the fraction of rows that actually pass the given qual conditions.

The *indexCorrelation* should be set to the correlation (ranging between -1.0 and 1.0) between the index order and the table order. This is used to adjust the estimate for the cost of fetching rows from the parent table.

The *indexPages* should be set to the number of leaf pages. This is used to estimate the number of workers for parallel index scan.

When *loop\_count* is greater than one, the returned numbers should be averages expected for any one scan of the index.

### Cost Estimation

A typical cost estimator will proceed as follows:

1. Estimate and return the fraction of parent-table rows that will be visited based on the given qual conditions. In the absence of any index-type-specific knowledge, use the standard optimizer function `clauselist_selectivity()`:

```
*indexSelectivity = clauselist_selectivity(root, path->indexquals,
                                           path->indexinfo->rel->relid,
                                           JOIN_INNER, NULL);
```

2. Estimate the number of index rows that will be visited during the scan. For many index types this is the same as *indexSelectivity* times the number of rows in the index, but it might be more. (Note that the index's size in pages and rows is available from the `path->indexinfo` struct.)
3. Estimate the number of index pages that will be retrieved during the scan. This might be just *indexSelectivity* times the index's size in pages.
4. Compute the index access cost. A generic estimator might do this:

```
/*
 * Our generic assumption is that the index pages will be read
 * sequentially, so they cost seq_page_cost each, not random_page_cost.
 * Also, we charge for evaluation of the indexquals at each index row.
 * All the costs are assumed to be paid incrementally during the scan.
 */
cost_qual_eval(&index_qual_cost, path->indexquals, root);
*indexStartupCost = index_qual_cost.startup;
*indexTotalCost = seq_page_cost * numIndexPages +
    (cpu_index_tuple_cost + index_qual_cost.per_tuple) * numIndexTuples;
```

However, the above does not account for amortization of index reads across repeated index scans.

5. Estimate the index correlation. For a simple ordered index on a single field, this can be retrieved from `pg_statistic`. If the correlation is not known, the conservative estimate is zero (no correlation).

---

## Chapter 63. Generic WAL Records

Although all built-in WAL-logged modules have their own types of WAL records, there is also a generic WAL record type, which describes changes to pages in a generic way. This is useful for extensions that provide custom access methods, because they cannot register their own WAL redo routines.

The API for constructing generic WAL records is defined in `access/generic_xlog.h` and implemented in `access/transam/generic_xlog.c`.

To perform a WAL-logged data update using the generic WAL record facility, follow these steps:

1. `state = GenericXLogStart(relation)` — start construction of a generic WAL record for the given relation.
2. `page = GenericXLogRegisterBuffer(state, buffer, flags)` — register a buffer to be modified within the current generic WAL record. This function returns a pointer to a temporary copy of the buffer's page, where modifications should be made. (Do not modify the buffer's contents directly.) The third argument is a bit mask of flags applicable to the operation. Currently the only such flag is `GENERIC_XLOG_FULL_IMAGE`, which indicates that a full-page image rather than a delta update should be included in the WAL record. Typically this flag would be set if the page is new or has been rewritten completely. `GenericXLogRegisterBuffer` can be repeated if the WAL-logged action needs to modify multiple pages.
3. Apply modifications to the page images obtained in the previous step.
4. `GenericXLogFinish(state)` — apply the changes to the buffers and emit the generic WAL record.

WAL record construction can be canceled between any of the above steps by calling `GenericXLogAbort(state)`. This will discard all changes to the page image copies.

Please note the following points when using the generic WAL record facility:

- No direct modifications of buffers are allowed! All modifications must be done in copies acquired from `GenericXLogRegisterBuffer()`. In other words, code that makes generic WAL records should never call `BufferGetPage()` for itself. However, it remains the caller's responsibility to pin/unpin and lock/unlock the buffers at appropriate times. Exclusive lock must be held on each target buffer from before `GenericXLogRegisterBuffer()` until after `GenericXLogFinish()`.
- Registrations of buffers (step 2) and modifications of page images (step 3) can be mixed freely, i.e., both steps may be repeated in any sequence. Keep in mind that buffers should be registered in the same order in which locks are to be obtained on them during replay.
- The maximum number of buffers that can be registered for a generic WAL record is `MAX_GENERIC_XLOG_PAGES`. An error will be thrown if this limit is exceeded.
- Generic WAL assumes that the pages to be modified have standard layout, and in particular that there is no useful data between `pd_lower` and `pd_upper`.
- Since you are modifying copies of buffer pages, `GenericXLogStart()` does not start a critical section. Thus, you can safely do memory allocation, error throwing, etc. between `GenericXLogStart()` and `GenericXLogFinish()`. The only actual critical section is present inside `GenericXLogFinish()`. There is no need to worry about calling `GenericXLogAbort()` during an error exit, either.
- `GenericXLogFinish()` takes care of marking buffers dirty and setting their LSNs. You do not need to do this explicitly.
- For unlogged relations, everything works the same except that no actual WAL record is emitted. Thus, you typically do not need to do any explicit checks for unlogged relations.
- The generic WAL redo function will acquire exclusive locks to buffers in the same order as they were registered. After redoing all changes, the locks will be released in the same order.
- If `GENERIC_XLOG_FULL_IMAGE` is not specified for a registered buffer, the generic WAL record contains a delta between the old and the new page images. This delta is based on byte-by-byte compar-

ison. This is not very compact for the case of moving data within a page, and might be improved in the future.

---

# Chapter 64. B-Tree Indexes

## 64.1. Introduction

Postgres Pro includes an implementation of the standard btree (multi-way balanced tree) index data structure. Any data type that can be sorted into a well-defined linear order can be indexed by a btree index. The only limitation is that an index entry cannot exceed approximately one-third of a page (after TOAST compression, if applicable).

Because each btree operator class imposes a sort order on its data type, btree operator classes (or, really, operator families) have come to be used as Postgres Pro's general representation and understanding of sorting semantics. Therefore, they've acquired some features that go beyond what would be needed just to support btree indexes, and parts of the system that are quite distant from the btree AM make use of them.

## 64.2. Behavior of B-Tree Operator Classes

As shown in [Table 40.3](#), a btree operator class must provide five comparison operators, `<`, `<=`, `=`, `>=` and `>`. One might expect that `<>` should also be part of the operator class, but it is not, because it would almost never be useful to use a `<>` WHERE clause in an index search. (For some purposes, the planner treats `<>` as associated with a btree operator class; but it finds that operator via the `=` operator's negator link, rather than from `pg_amop`.)

When several data types share near-identical sorting semantics, their operator classes can be grouped into an operator family. Doing so is advantageous because it allows the planner to make deductions about cross-type comparisons. Each operator class within the family should contain the single-type operators (and associated support functions) for its input data type, while cross-type comparison operators and support functions are “loose” in the family. It is recommendable that a complete set of cross-type operators be included in the family, thus ensuring that the planner can represent any comparison conditions that it deduces from transitivity.

There are some basic assumptions that a btree operator family must satisfy:

- An `=` operator must be an equivalence relation; that is, for all non-null values *A*, *B*, *C* of the data type:
  - *A* = *A* is true (*reflexive law*)
  - if *A* = *B*, then *B* = *A* (*symmetric law*)
  - if *A* = *B* and *B* = *C*, then *A* = *C* (*transitive law*)
- A `<` operator must be a strong ordering relation; that is, for all non-null values *A*, *B*, *C*:
  - *A* < *A* is false (*irreflexive law*)
  - if *A* < *B* and *B* < *C*, then *A* < *C* (*transitive law*)
- Furthermore, the ordering is total; that is, for all non-null values *A*, *B*:
  - exactly one of *A* < *B*, *A* = *B*, and *B* < *A* is true (*trichotomy law*)

(The trichotomy law justifies the definition of the comparison support function, of course.)

The other three operators are defined in terms of `=` and `<` in the obvious way, and must act consistently with them.

For an operator family supporting multiple data types, the above laws must hold when *A*, *B*, *C* are taken from any data types in the family. The transitive laws are the trickiest to ensure, as in cross-type situations they represent statements that the behaviors of two or three different operators are consistent. As an example, it would not work to put `float8` and `numeric` into the same operator family, at least not with the current semantics that `numeric` values are converted to `float8` for comparison to a `float8`. Because

of the limited accuracy of `float8`, this means there are distinct `numeric` values that will compare equal to the same `float8` value, and thus the transitive law would fail.

Another requirement for a multiple-data-type family is that any implicit or binary-coercion casts that are defined between data types included in the operator family must not change the associated sort ordering.

It should be fairly clear why a btree index requires these laws to hold within a single data type: without them there is no ordering to arrange the keys with. Also, index searches using a comparison key of a different data type require comparisons to behave sanely across two data types. The extensions to three or more data types within a family are not strictly required by the btree index mechanism itself, but the planner relies on them for optimization purposes.

To implement the distance ordered (nearest-neighbor) search, we only need to define a distance operator (usually called `<->`) with the corresponding operator family for distance comparison in the index's operator class. These operators must satisfy the following assumptions for all non-null values *A*, *B*, *C* of the datatype:

- $A <-> B = B <-> A$  (*symmetric law*)
- if  $A = B$ , then  $A <-> C = B <-> C$  (*distance equivalence*)
- if  $(A \leq B \text{ and } B \leq C)$  or  $(A \geq B \text{ and } B \geq C)$ , then  $A <-> B \leq A <-> C$  (*monotonicity*)

## 64.3. B-Tree Support Functions

As shown in [Table 40.9](#), btree defines one required and four optional support functions. The five user-defined methods are:

`order`

For each combination of data types that a btree operator family provides comparison operators for, it must provide a comparison support function, registered in `pg_amproc` with support function number 1 and `amproclefttype/amprocrighttype` equal to the left and right data types for the comparison (i.e., the same data types that the matching operators are registered with in `pg_amop`). The comparison function must take two non-null values *A* and *B* and return an `int32` value that is `< 0`, `0`, or `> 0` when  $A < B$ ,  $A = B$ , or  $A > B$ , respectively. A null result is disallowed: all values of the data type must be comparable.

If the compared values are of a collatable data type, the appropriate collation OID will be passed to the comparison support function, using the standard `PG_GET_COLLATION()` mechanism.

`sortsupport`

Optionally, a btree operator family may provide *sort support* function(s), registered under support function number 2. These functions allow implementing comparisons for sorting purposes in a more efficient way than naively calling the comparison support function. The APIs involved in this are defined in [src/include/utils/sortsupport.h](#).

`in_range`

Optionally, a btree operator family may provide *in\_range* support function(s), registered under support function number 3. These are not used during btree index operations; rather, they extend the semantics of the operator family so that it can support window clauses containing the `RANGE offset PRECEDING` and `RANGE offset FOLLOWING` frame bound types (see [Section 4.2.8](#)). Fundamentally, the extra information provided is how to add or subtract an *offset* value in a way that is compatible with the family's data ordering.

An `in_range` function must have the signature

```
in_range(val type1, base type1, offset type2, sub bool, less bool)
returns bool
```

*val* and *base* must be of the same type, which is one of the types supported by the operator family (i.e., a type for which it provides an ordering). However, *offset* could be of a different type, which might be one otherwise unsupported by the family. An example is that the built-in `time_ops` family provides an `in_range` function that has *offset* of type `interval`. A family can provide `in_range` functions for any of its supported types and one or more *offset* types. Each `in_range` function should be entered in `pg_amproc` with `amproclefttype` equal to `type1` and `amprocrighttype` equal to `type2`.

The essential semantics of an `in_range` function depend on the two Boolean flag parameters. It should add or subtract *base* and *offset*, then compare *val* to the result, as follows:

- if *!sub* and *!less*, return `val >= (base + offset)`
- if *!sub* and *less*, return `val <= (base + offset)`
- if *sub* and *!less*, return `val >= (base - offset)`
- if *sub* and *less*, return `val <= (base - offset)`

Before doing so, the function should check the sign of *offset*: if it is less than zero, raise error `ERCODE_INVALID_PRECEDING_OR_FOLLOWING_SIZE` (22013) with error text like “invalid preceding or following size in window function”. (This is required by the SQL standard, although nonstandard operator families might perhaps choose to ignore this restriction, since there seems to be little semantic necessity for it.) This requirement is delegated to the `in_range` function so that the core code needn't understand what “less than zero” means for a particular data type.

An additional expectation is that `in_range` functions should, if practical, avoid throwing an error if `base + offset` or `base - offset` would overflow. The correct comparison result can be determined even if that value would be out of the data type's range. Note that if the data type includes concepts such as “infinity” or “NaN”, extra care may be needed to ensure that `in_range`'s results agree with the normal sort order of the operator family.

The results of the `in_range` function must be consistent with the sort ordering imposed by the operator family. To be precise, given any fixed values of *offset* and *sub*, then:

- If `in_range` with *less* = true is true for some *val1* and *base*, it must be true for every *val2* <= *val1* with the same *base*.
- If `in_range` with *less* = true is false for some *val1* and *base*, it must be false for every *val2* >= *val1* with the same *base*.
- If `in_range` with *less* = true is true for some *val* and *base1*, it must be true for every *base2* >= *base1* with the same *val*.
- If `in_range` with *less* = true is false for some *val* and *base1*, it must be false for every *base2* <= *base1* with the same *val*.

Analogous statements with inverted conditions hold when *less* = false.

If the type being ordered (*type1*) is collatable, the appropriate collation OID will be passed to the `in_range` function, using the standard `PG_GET_COLLATION()` mechanism.

`in_range` functions need not handle NULL inputs, and typically will be marked strict.

#### `equalimage`

Optionally, a btree operator family may provide `equalimage` (“equality implies image equality”) support functions, registered under support function number 4. These functions allow the core code to determine when it is safe to apply the btree deduplication optimization. Currently, `equalimage` functions are only called when building or rebuilding an index.

An `equalimage` function must have the signature

```
equalimage(opcintype oid) returns bool
```

The return value is static information about an operator class and collation. Returning `true` indicates that the `order` function for the operator class is guaranteed to only return 0 (“arguments are equal”) when its *A* and *B* arguments are also interchangeable without any loss of semantic information. Not registering an `equalimage` function or returning `false` indicates that this condition cannot be assumed to hold.

The `opcintype` argument is the `pg_type.oid` of the data type that the operator class indexes. This is a convenience that allows reuse of the same underlying `equalimage` function across operator classes. If `opcintype` is a collatable data type, the appropriate collation OID will be passed to the `equalimage` function, using the standard `PG_GET_COLLATION()` mechanism.

As far as the operator class is concerned, returning `true` indicates that deduplication is safe (or safe for the collation whose OID was passed to its `equalimage` function). However, the core code will only deem deduplication safe for an index when *every* indexed column uses an operator class that registers an `equalimage` function, and each function actually returns `true` when called.

Image equality is *almost* the same condition as simple bitwise equality. There is one subtle difference: When indexing a varlena data type, the on-disk representation of two image equal datums may not be bitwise equal due to inconsistent application of TOAST compression on input. Formally, when an operator class's `equalimage` function returns `true`, it is safe to assume that the `datum_image_eq()` C function will always agree with the operator class's `order` function (provided that the same collation OID is passed to both the `equalimage` and `order` functions).

The core code is fundamentally unable to deduce anything about the “equality implies image equality” status of an operator class within a multiple-data-type family based on details from other operator classes in the same family. Also, it is not sensible for an operator family to register a cross-type `equalimage` function, and attempting to do so will result in an error. This is because “equality implies image equality” status does not just depend on sorting/equality semantics, which are more or less defined at the operator family level. In general, the semantics that one particular data type implements must be considered separately.

The convention followed by the operator classes included with the core Postgres Pro distribution is to register a stock, generic `equalimage` function. Most operator classes register `btequalimage()`, which indicates that deduplication is safe unconditionally. Operator classes for collatable data types such as `text` register `btvarstrequalimage()`, which indicates that deduplication is safe with deterministic collations. Best practice for third-party extensions is to register their own custom function to retain control.

#### options

Optionally, a B-tree operator family may provide `options` (“operator class specific options”) support functions, registered under support function number 5. These functions define a set of user-visible parameters that control operator class behavior.

An `options` support function must have the signature

```
options(relopts local_relopts *) returns void
```

The function is passed a pointer to a `local_relopts` struct, which needs to be filled with a set of operator class specific options. The options can be accessed from other support functions using the `PG_HAS_OPCLASS_OPTIONS()` and `PG_GET_OPCLASS_OPTIONS()` macros.

Currently, no B-Tree operator class has an `options` support function. B-tree doesn't allow flexible representation of keys like GiST, SP-GiST, GIN and BRIN do. So, `options` probably doesn't have much application in the current B-tree index access method. Nevertheless, this support function was added to B-tree for uniformity, and will probably find uses during further evolution of B-tree in Postgres Pro.

## 64.4. Implementation

This section covers B-Tree index implementation details that may be of use to advanced users.

### 64.4.1. B-Tree Structure

Postgres Pro Enterprise B-Tree indexes are multi-level tree structures, where each level of the tree can be used as a doubly-linked list of pages. A single metapage is stored in a fixed position at the start of the first segment file of the index. All other pages are either leaf pages or internal pages. Leaf pages are the pages on the lowest level of the tree. All other levels consist of internal pages. Each leaf page contains tuples that point to table rows. Each internal page contains tuples that point to the next level down in the tree. Typically, over 99% of all pages are leaf pages. Both internal pages and leaf pages use the standard page format described in [Section 70.6](#).

New leaf pages are added to a B-Tree index when an existing leaf page cannot fit an incoming tuple. A *page split* operation makes room for items that originally belonged on the overflowing page by moving a portion of the items to a new page. Page splits must also insert a new *downlink* to the new page in the parent page, which may cause the parent to split in turn. Page splits “cascade upwards” in a recursive fashion. When the root page finally cannot fit a new downlink, a *root page split* operation takes place. This adds a new level to the tree structure by creating a new root page that is one level above the original root page.

### 64.4.2. Bottom-up Index Deletion

B-Tree indexes are not directly aware that under MVCC, there might be multiple extant versions of the same logical table row; to an index, each tuple is an independent object that needs its own index entry. “Version churn” tuples may sometimes accumulate and adversely affect query latency and throughput. This typically occurs with `UPDATE`-heavy workloads where most individual updates cannot apply the [HOT optimization](#). Changing the value of only one column covered by one index during an `UPDATE` *always* necessitates a new set of index tuples — one for *each and every* index on the table. Note in particular that this includes indexes that were not “logically modified” by the `UPDATE`. All indexes will need a successor physical index tuple that points to the latest version in the table. Each new tuple within each index will generally need to coexist with the original “updated” tuple for a short period of time (typically until shortly after the `UPDATE` transaction commits).

B-Tree indexes incrementally delete version churn index tuples by performing *bottom-up index deletion* passes. Each deletion pass is triggered in reaction to an anticipated “version churn page split”. This only happens with indexes that are not logically modified by `UPDATE` statements, where concentrated build up of obsolete versions in particular pages would occur otherwise. A page split will usually be avoided, though it's possible that certain implementation-level heuristics will fail to identify and delete even one garbage index tuple (in which case a page split or deduplication pass resolves the issue of an incoming new tuple not fitting on a leaf page). The worst-case number of versions that any index scan must traverse (for any single logical row) is an important contributor to overall system responsiveness and throughput. A bottom-up index deletion pass targets suspected garbage tuples in a single leaf page based on *qualitative* distinctions involving logical rows and versions. This contrasts with the “top-down” index cleanup performed by autovacuum workers, which is triggered when certain *quantitative* table-level thresholds are exceeded (see [Section 24.1.6](#)).

#### Note

Not all deletion operations that are performed within B-Tree indexes are bottom-up deletion operations. There is a distinct category of index tuple deletion: *simple index tuple deletion*. This is a deferred maintenance operation that deletes index tuples that are known to be safe to delete (those whose item identifier's `LP_DEAD` bit is already set). Like bottom-up index deletion, simple index deletion takes place at the point that a page split is anticipated as a way of avoiding the split.

Simple deletion is opportunistic in the sense that it can only take place when recent index scans set the `LP_DEAD` bits of affected items in passing. Prior to PostgreSQL 14, the only category of B-Tree deletion was simple deletion. The main differences between it and bottom-up deletion are that only the former is opportunistically driven by the activity of passing index scans, while only the latter specifically targets version churn from `UPDATES` that do not logically modify indexed columns.

Bottom-up index deletion performs the vast majority of all garbage index tuple cleanup for particular indexes with certain workloads. This is expected with any B-Tree index that is subject to significant version churn from `UPDATE`s that rarely or never logically modify the columns that the index covers. The average and worst-case number of versions per logical row can be kept low purely through targeted incremental deletion passes. It's quite possible that the on-disk size of certain indexes will never increase by even one single page/block despite *constant* version churn from `UPDATE`s. Even then, an exhaustive “clean sweep” by a `VACUUM` operation (typically run in an autovacuum worker process) will eventually be required as a part of *collective* cleanup of the table and each of its indexes.

Unlike `VACUUM`, bottom-up index deletion does not provide any strong guarantees about how old the oldest garbage index tuple may be. No index can be permitted to retain “floating garbage” index tuples that became dead prior to a conservative cutoff point shared by the table and all of its indexes collectively. This fundamental table-level invariant makes it safe to recycle table TIDs. This is how it is possible for distinct logical rows to reuse the same table TID over time (though this can never happen with two logical rows whose lifetimes span the same `VACUUM` cycle).

### 64.4.3. Deduplication

A duplicate is a leaf page tuple (a tuple that points to a table row) where *all* indexed key columns have values that match corresponding column values from at least one other leaf page tuple in the same index. Duplicate tuples are quite common in practice. B-Tree indexes can use a special, space-efficient representation for duplicates when an optional technique is enabled: *deduplication*.

Deduplication works by periodically merging groups of duplicate tuples together, forming a single *posting list* tuple for each group. The column key value(s) only appear once in this representation. This is followed by a sorted array of TIDs that point to rows in the table. This significantly reduces the storage size of indexes where each value (or each distinct combination of column values) appears several times on average. The latency of queries can be reduced significantly. Overall query throughput may increase significantly. The overhead of routine index vacuuming may also be reduced significantly.

#### Note

B-Tree deduplication is just as effective with “duplicates” that contain a `NULL` value, even though `NULL` values are never equal to each other according to the `=` member of any B-Tree operator class. As far as any part of the implementation that understands the on-disk B-Tree structure is concerned, `NULL` is just another value from the domain of indexed values.

The deduplication process occurs lazily, when a new item is inserted that cannot fit on an existing leaf page, though only when index tuple deletion could not free sufficient space for the new item (typically deletion is briefly considered and then skipped over). Unlike GIN posting list tuples, B-Tree posting list tuples do not need to expand every time a new duplicate is inserted; they are merely an alternative physical representation of the original logical contents of the leaf page. This design prioritizes consistent performance with mixed read-write workloads. Most client applications will at least see a moderate performance benefit from using deduplication. Deduplication is enabled by default.

`CREATE INDEX` and `REINDEX` apply deduplication to create posting list tuples, though the strategy they use is slightly different. Each group of duplicate ordinary tuples encountered in the sorted input taken from the table is merged into a posting list tuple *before* being added to the current pending leaf page. Individual posting list tuples are packed with as many TIDs as possible. Leaf pages are written out in the usual way, without any separate deduplication pass. This strategy is well-suited to `CREATE INDEX` and `REINDEX` because they are once-off batch operations.

Write-heavy workloads that don't benefit from deduplication due to having few or no duplicate values in indexes will incur a small, fixed performance penalty (unless deduplication is explicitly disabled). The `deduplicate_items` storage parameter can be used to disable deduplication within individual indexes. There is never any performance penalty with read-only workloads, since reading posting list tuples is at least as efficient as reading the standard tuple representation. Disabling deduplication isn't usually helpful.

It is sometimes possible for unique indexes (as well as unique constraints) to use deduplication. This allows leaf pages to temporarily “absorb” extra version churn duplicates. Deduplication in unique indexes augments bottom-up index deletion, especially in cases where a long-running transaction holds a snapshot that blocks garbage collection. The goal is to buy time for the bottom-up index deletion strategy to become effective again. Delaying page splits until a single long-running transaction naturally goes away can allow a bottom-up deletion pass to succeed where an earlier deletion pass failed.

### Tip

A special heuristic is applied to determine whether a deduplication pass in a unique index should take place. It can often skip straight to splitting a leaf page, avoiding a performance penalty from wasting cycles on unhelpful deduplication passes. If you're concerned about the overhead of deduplication, consider setting `deduplicate_items = off` selectively. Leaving deduplication enabled in unique indexes has little downside.

Deduplication cannot be used in all cases due to implementation-level restrictions. Deduplication safety is determined when `CREATE INDEX` or `REINDEX` is run.

Note that deduplication is deemed unsafe and cannot be used in the following cases involving semantically significant differences among equal datums:

- `text`, `varchar`, and `char` cannot use deduplication when a *nondeterministic* collation is used. Case and accent differences must be preserved among equal datums.
- `numeric` cannot use deduplication. Numeric display scale must be preserved among equal datums.
- `jsonb` cannot use deduplication, since the `jsonb` B-Tree operator class uses `numeric` internally.
- `float4` and `float8` cannot use deduplication. These types have distinct representations for `-0` and `0`, which are nevertheless considered equal. This difference must be preserved.

There is one further implementation-level restriction that may be lifted in a future version of Postgres Pro Enterprise:

- Container types (such as composite types, arrays, or range types) cannot use deduplication.

There is one further implementation-level restriction that applies regardless of the operator class or collation used:

- `INCLUDE` indexes can never use deduplication.

# Chapter 65. GiST Indexes

## 65.1. Introduction

GiST stands for Generalized Search Tree. It is a balanced, tree-structured access method, that acts as a base template in which to implement arbitrary indexing schemes. B-trees, R-trees and many other indexing schemes can be implemented in GiST.

One advantage of GiST is that it allows the development of custom data types with the appropriate access methods, by an expert in the domain of the data type, rather than a database expert.

Some of the information here is derived from the University of California at Berkeley's GiST Indexing Project [web site](#) and Marcel Kornacker's thesis, [Access Methods for Next-Generation Database Systems](#). The GiST implementation in Postgres Pro is primarily maintained by Teodor Sigaev and Oleg Bartunov, and there is more information on their [web site](#).

## 65.2. Built-in Operator Classes

The core Postgres Pro distribution includes the GiST operator classes shown in [Table 65.1](#). (Some of the optional modules described in [Appendix F](#) provide additional GiST operator classes.)

**Table 65.1. Built-in GiST Operator Classes**

| Name       | Indexable Operators  | Ordering Operators  |
|------------|----------------------|---------------------|
| box_ops    | << (box, box)        | <-> (box, point)    |
|            | &< (box, box)        |                     |
|            | && (box, box)        |                     |
|            | &> (box, box)        |                     |
|            | >> (box, box)        |                     |
|            | ~= (box, box)        |                     |
|            | @> (box, box)        |                     |
|            | <@ (box, box)        |                     |
|            | &<  (box, box)       |                     |
|            | <<  (box, box)       |                     |
|            | >> (box, box)        |                     |
|            | &> (box, box)        |                     |
| circle_ops | << (circle, circle)  | <-> (circle, point) |
|            | &< (circle, circle)  |                     |
|            | &> (circle, circle)  |                     |
|            | >> (circle, circle)  |                     |
|            | <@ (circle, circle)  |                     |
|            | @> (circle, circle)  |                     |
|            | ~= (circle, circle)  |                     |
|            | && (circle, circle)  |                     |
|            | >> (circle, circle)  |                     |
|            | <<  (circle, circle) |                     |
|            | &<  (circle, circle) |                     |
|            | &> (circle, circle)  |                     |

| Name           | Indexable Operators                | Ordering Operators   |
|----------------|------------------------------------|----------------------|
| inet_ops       | << (inet, inet)                    |                      |

| tsquery_ops  | <@ (tsquery, tsquery)         |                    |
|              | @> (tsquery, tsquery)         |                    |
| tsvector_ops | @@ (tsvector, tsquery)        |                    |

For historical reasons, the `inet_ops` operator class is not the default class for types `inet` and `cidr`. To use it, mention the class name in `CREATE INDEX`, for example

```
CREATE INDEX ON my_table USING GIST (my_inet_column inet_ops);
```

## 65.3. Extensibility

Traditionally, implementing a new index access method meant a lot of difficult work. It was necessary to understand the inner workings of the database, such as the lock manager and Write-Ahead Log. The GiST interface has a high level of abstraction, requiring the access method implementer only to implement the semantics of the data type being accessed. The GiST layer itself takes care of concurrency, logging and searching the tree structure.

This extensibility should not be confused with the extensibility of the other standard search trees in terms of the data they can handle. For example, Postgres Pro supports extensible B-trees and hash indexes.

That means that you can use Postgres Pro to build a B-tree or hash over any data type you want. But B-trees only support range predicates ( $<$ ,  $=$ ,  $>$ ), and hash indexes only support equality queries.

So if you index, say, an image collection with a Postgres Pro B-tree, you can only issue queries such as “is imagex equal to imagey”, “is imagex less than imagey” and “is imagex greater than imagey”. Depending on how you define “equals”, “less than” and “greater than” in this context, this could be useful. However, by using a GiST based index, you could create ways to ask domain-specific questions, perhaps “find all images of horses” or “find all over-exposed images”.

All it takes to get a GiST access method up and running is to implement several user-defined methods, which define the behavior of keys in the tree. Of course these methods have to be pretty fancy to support fancy queries, but for all the standard queries (B-trees, R-trees, etc.) they're relatively straightforward. In short, GiST combines extensibility along with generality, code reuse, and a clean interface.

There are five methods that an index operator class for GiST must provide, and six that are optional. Correctness of the index is ensured by proper implementation of the `same`, `consistent` and `union` methods, while efficiency (size and speed) of the index will depend on the `penalty` and `picksplit` methods. Two optional methods are `compress` and `decompress`, which allow an index to have internal tree data of a different type than the data it indexes. The leaves are to be of the indexed data type, while the other tree nodes can be of any C struct (but you still have to follow Postgres Pro data type rules here, see about `varlena` for variable sized data). If the tree's internal data type exists at the SQL level, the `STORAGE` option of the `CREATE OPERATOR CLASS` command can be used. The optional eighth method is `distance`, which is needed if the operator class wishes to support ordered scans (nearest-neighbor searches). The optional ninth method `fetch` is needed if the operator class wishes to support index-only scans, except when the `compress` method is omitted. The optional tenth method `options` is needed if the operator class has user-specified parameters. The optional eleventh method `sortsupport` is used to speed up building a GiST index.

`consistent`

Given an index entry  $p$  and a query value  $q$ , this function determines whether the index entry is “consistent” with the query; that is, could the predicate “`indexed_column indexable_operator q`” be true for any row represented by the index entry? For a leaf index entry this is equivalent to testing the indexable condition, while for an internal tree node this determines whether it is necessary to scan the subtree of the index represented by the tree node. When the result is `true`, a `recheck` flag must also be returned. This indicates whether the predicate is certainly true or only possibly true. If `recheck = false` then the index has tested the predicate condition exactly, whereas if `recheck = true` the row is only a candidate match. In that case the system will automatically evaluate the `indexable_operator` against the actual row value to see if it is really a match. This convention allows GiST to support both lossless and lossy index structures.

The SQL declaration of the function must look like this:

```
CREATE OR REPLACE FUNCTION my_consistent(internal, data_type, smallint, oid,
    internal)
RETURNS bool
AS 'MODULE_PATHNAME'
LANGUAGE C STRICT;
```

And the matching code in the C module could then follow this skeleton:

```
PG_FUNCTION_INFO_V1(my_consistent);

Datum
my_consistent(PG_FUNCTION_ARGS)
{
    GISTENTRY *entry = (GISTENTRY *) PG_GETARG_POINTER(0);
    data_type *query = PG_GETARG_DATA_TYPE_P(1);
    StrategyNumber strategy = (StrategyNumber) PG_GETARG_UINT16(2);
    /* Oid subtype = PG_GETARG_OID(3); */
    bool *recheck = (bool *) PG_GETARG_POINTER(4);
```

```
data_type *key = DatumGetDataType(entry->key);
bool      retval;

/*
 * determine return value as a function of strategy, key and query.
 *
 * Use GIST_LEAF(entry) to know where you're called in the index tree,
 * which comes handy when supporting the = operator for example (you could
 * check for non empty union() in non-leaf nodes and equality in leaf
 * nodes).
 */

*recheck = true;          /* or false if check is exact */

PG_RETURN_BOOL(retval);
}
```

Here, `key` is an element in the index and `query` the value being looked up in the index. The `StrategyNumber` parameter indicates which operator of your operator class is being applied — it matches one of the operator numbers in the `CREATE OPERATOR CLASS` command.

Depending on which operators you have included in the class, the data type of `query` could vary with the operator, since it will be whatever type is on the right-hand side of the operator, which might be different from the indexed data type appearing on the left-hand side. (The above code skeleton assumes that only one type is possible; if not, fetching the `query` argument value would have to depend on the operator.) It is recommended that the SQL declaration of the `consistent` function use the opclass's indexed data type for the `query` argument, even though the actual type might be something else depending on the operator.

#### union

This method consolidates information in the tree. Given a set of entries, this function generates a new index entry that represents all the given entries.

The SQL declaration of the function must look like this:

```
CREATE OR REPLACE FUNCTION my_union(internal, internal)
RETURNS storage_type
AS 'MODULE_PATHNAME'
LANGUAGE C STRICT;
```

And the matching code in the C module could then follow this skeleton:

```
PG_FUNCTION_INFO_V1(my_union);

Datum
my_union(PG_FUNCTION_ARGS)
{
    GistEntryVector *entryvec = (GistEntryVector *) PG_GETARG_POINTER(0);
    GISTENTRY *ent = entryvec->vector;
    data_type *out,
              *tmp,
              *old;
    int      numranges,
            i = 0;

    numranges = entryvec->n;
    tmp = DatumGetDataType(ent[0].key);
    out = tmp;

    if (numranges == 1)
    {
```

```
        out = data_type_deep_copy(tmp);

        PG_RETURN_DATA_TYPE_P(out);
    }

    for (i = 1; i < numranges; i++)
    {
        old = out;
        tmp = DatumGetDataType(ent[i].key);
        out = my_union_implementation(out, tmp);
    }

    PG_RETURN_DATA_TYPE_P(out);
}
```

As you can see, in this skeleton we're dealing with a data type where `union(X, Y, Z) = union(union(X, Y), Z)`. It's easy enough to support data types where this is not the case, by implementing the proper union algorithm in this GiST support method.

The result of the `union` function must be a value of the index's storage type, whatever that is (it might or might not be different from the indexed column's type). The `union` function should return a pointer to newly `palloc()`ed memory. You can't just return the input value as-is, even if there is no type change.

As shown above, the `union` function's first internal argument is actually a `GistEntryVector` pointer. The second argument is a pointer to an integer variable, which can be ignored. (It used to be required that the `union` function store the size of its result value into that variable, but this is no longer necessary.)

#### `compress`

Converts a data item into a format suitable for physical storage in an index page. If the `compress` method is omitted, data items are stored in the index without modification.

The SQL declaration of the function must look like this:

```
CREATE OR REPLACE FUNCTION my_compress(internal)
RETURNS internal
AS 'MODULE_PATHNAME'
LANGUAGE C STRICT;
```

And the matching code in the C module could then follow this skeleton:

```
PG_FUNCTION_INFO_V1(my_compress);

Datum
my_compress(PG_FUNCTION_ARGS)
{
    GISTENTRY *entry = (GISTENTRY *) PG_GETARG_POINTER(0);
    GISTENTRY *retval;

    if (entry->leafkey)
    {
        /* replace entry->key with a compressed version */
        compressed_data_type *compressed_data =
            palloc(sizeof(compressed_data_type));

        /* fill *compressed_data from entry->key ... */

        retval = palloc(sizeof(GISTENTRY));
        gistentryinit(retval, PointerGetDatum(compressed_data),
                      entry->rel, entry->page, entry->offset, FALSE);
    }
}
```

```
    }
    else
    {
        /* typically we needn't do anything with non-leaf entries */
        retval = entry;
    }

    PG_RETURN_POINTER(retval);
}
```

You have to adapt *compressed\_data\_type* to the specific type you're converting to in order to compress your leaf nodes, of course.

#### decompress

Converts the stored representation of a data item into a format that can be manipulated by the other GiST methods in the operator class. If the `decompress` method is omitted, it is assumed that the other GiST methods can work directly on the stored data format. (`decompress` is not necessarily the reverse of the `compress` method; in particular, if `compress` is lossy then it's impossible for `decompress` to exactly reconstruct the original data. `decompress` is not necessarily equivalent to `fetch`, either, since the other GiST methods might not require full reconstruction of the data.)

The SQL declaration of the function must look like this:

```
CREATE OR REPLACE FUNCTION my_decompress(internal)
RETURNS internal
AS 'MODULE_PATHNAME'
LANGUAGE C STRICT;
```

And the matching code in the C module could then follow this skeleton:

```
PG_FUNCTION_INFO_V1(my_decompress);

Datum
my_decompress(PG_FUNCTION_ARGS)
{
    PG_RETURN_POINTER(PG_GETARG_POINTER(0));
}
```

The above skeleton is suitable for the case where no decompression is needed. (But, of course, omitting the method altogether is even easier, and is recommended in such cases.)

#### penalty

Returns a value indicating the “cost” of inserting the new entry into a particular branch of the tree. Items will be inserted down the path of least `penalty` in the tree. Values returned by `penalty` should be non-negative. If a negative value is returned, it will be treated as zero.

The SQL declaration of the function must look like this:

```
CREATE OR REPLACE FUNCTION my_penalty(internal, internal, internal)
RETURNS internal
AS 'MODULE_PATHNAME'
LANGUAGE C STRICT; -- in some cases penalty functions need not be strict
```

And the matching code in the C module could then follow this skeleton:

```
PG_FUNCTION_INFO_V1(my_penalty);

Datum
my_penalty(PG_FUNCTION_ARGS)
{
    GISTENTRY *origentry = (GISTENTRY *) PG_GETARG_POINTER(0);
    GISTENTRY *newentry = (GISTENTRY *) PG_GETARG_POINTER(1);
    float      *penalty = (float *) PG_GETARG_POINTER(2);
}
```

```
data_type *orig = DatumGetDataType(origentry->key);
data_type *new = DatumGetDataType(newentry->key);

*penalty = my_penalty_implementation(orig, new);
PG_RETURN_POINTER(penalty);
}
```

For historical reasons, the `penalty` function doesn't just return a `float` result; instead it has to store the value at the location indicated by the third argument. The return value per se is ignored, though it's conventional to pass back the address of that argument.

The `penalty` function is crucial to good performance of the index. It'll get used at insertion time to determine which branch to follow when choosing where to add the new entry in the tree. At query time, the more balanced the index, the quicker the lookup.

#### `picksplit`

When an index page split is necessary, this function decides which entries on the page are to stay on the old page, and which are to move to the new page.

The SQL declaration of the function must look like this:

```
CREATE OR REPLACE FUNCTION my_picksplit(internal, internal)
RETURNS internal
AS 'MODULE_PATHNAME'
LANGUAGE C STRICT;
```

And the matching code in the C module could then follow this skeleton:

```
PG_FUNCTION_INFO_V1(my_picksplit);

Datum
my_picksplit(PG_FUNCTION_ARGS)
{
    GistEntryVector *entryvec = (GistEntryVector *) PG_GETARG_POINTER(0);
    GIST_SPLITVEC *v = (GIST_SPLITVEC *) PG_GETARG_POINTER(1);
    OffsetNumber maxoff = entryvec->n - 1;
    GISTENTRY *ent = entryvec->vector;
    int i,
        nbytes;
    OffsetNumber *left,
        *right;
    data_type *tmp_union;
    data_type *unionL;
    data_type *unionR;
    GISTENTRY **raw_entryvec;

    maxoff = entryvec->n - 1;
    nbytes = (maxoff + 1) * sizeof(OffsetNumber);

    v->spl_left = (OffsetNumber *) palloc(nbytes);
    left = v->spl_left;
    v->spl_nleft = 0;

    v->spl_right = (OffsetNumber *) palloc(nbytes);
    right = v->spl_right;
    v->spl_nright = 0;

    unionL = NULL;
    unionR = NULL;

    /* Initialize the raw entry vector. */
```

```
raw_entryvec = (GISTENTRY **) malloc(entryvec->n * sizeof(void *));
for (i = FirstOffsetNumber; i <= maxoff; i = OffsetNumberNext(i))
    raw_entryvec[i] = &(entryvec->vector[i]);

for (i = FirstOffsetNumber; i <= maxoff; i = OffsetNumberNext(i))
{
    int          real_index = raw_entryvec[i] - entryvec->vector;

    tmp_union = DatumGetDataTypes(entryvec->vector[real_index].key);
    Assert(tmp_union != NULL);

    /*
     * Choose where to put the index entries and update unionL and unionR
     * accordingly. Append the entries to either v->spl_left or
     * v->spl_right, and care about the counters.
     */

    if (my_choice_is_left(unionL, curl, unionR, curr))
    {
        if (unionL == NULL)
            unionL = tmp_union;
        else
            unionL = my_union_implementation(unionL, tmp_union);

        *left = real_index;
        ++left;
        ++(v->spl_nleft);
    }
    else
    {
        /*
         * Same on the right
         */
    }
}

v->spl_ldatum = DataTypeGetDatum(unionL);
v->spl_rdatum = DataTypeGetDatum(unionR);
PG_RETURN_POINTER(v);
}
```

Notice that the `picksplit` function's result is delivered by modifying the passed-in `v` structure. The return value per se is ignored, though it's conventional to pass back the address of `v`.

Like `penalty`, the `picksplit` function is crucial to good performance of the index. Designing suitable `penalty` and `picksplit` implementations is where the challenge of implementing well-performing GiST indexes lies.

same

Returns true if two index entries are identical, false otherwise. (An "index entry" is a value of the index's storage type, not necessarily the original indexed column's type.)

The SQL declaration of the function must look like this:

```
CREATE OR REPLACE FUNCTION my_same(storage_type, storage_type, internal)
RETURNS internal
AS 'MODULE_PATHNAME'
LANGUAGE C STRICT;
```

And the matching code in the C module could then follow this skeleton:

```
PG_FUNCTION_INFO_V1(my_same);

Datum
my_same(PG_FUNCTION_ARGS)
{
    prefix_range *v1 = PG_GETARG_PREFIX_RANGE_P(0);
    prefix_range *v2 = PG_GETARG_PREFIX_RANGE_P(1);
    bool          *result = (bool *) PG_GETARG_POINTER(2);

    *result = my_eq(v1, v2);
    PG_RETURN_POINTER(result);
}
```

For historical reasons, the `same` function doesn't just return a Boolean result; instead it has to store the flag at the location indicated by the third argument. The return value per se is ignored, though it's conventional to pass back the address of that argument.

`distance`

Given an index entry `p` and a query value `q`, this function determines the index entry's “distance” from the query value. This function must be supplied if the operator class contains any ordering operators. A query using the ordering operator will be implemented by returning index entries with the smallest “distance” values first, so the results must be consistent with the operator's semantics. For a leaf index entry the result just represents the distance to the index entry; for an internal tree node, the result must be the smallest distance that any child entry could have.

The SQL declaration of the function must look like this:

```
CREATE OR REPLACE FUNCTION my_distance(internal, data_type, smallint, oid, internal)
RETURNS float8
AS 'MODULE_PATHNAME'
LANGUAGE C STRICT;
```

And the matching code in the C module could then follow this skeleton:

```
PG_FUNCTION_INFO_V1(my_distance);

Datum
my_distance(PG_FUNCTION_ARGS)
{
    GISTENTRY *entry = (GISTENTRY *) PG_GETARG_POINTER(0);
    data_type *query = PG_GETARG_DATA_TYPE_P(1);
    StrategyNumber strategy = (StrategyNumber) PG_GETARG_UINT16(2);
    /* Oid subtype = PG_GETARG_OID(3); */
    /* bool *recheck = (bool *) PG_GETARG_POINTER(4); */
    data_type *key = DatumGetDataTypes(entry->key);
    double      retval;

    /*
     * determine return value as a function of strategy, key and query.
     */

    PG_RETURN_FLOAT8(retval);
}
```

The arguments to the `distance` function are identical to the arguments of the `consistent` function.

Some approximation is allowed when determining the distance, so long as the result is never greater than the entry's actual distance. Thus, for example, distance to a bounding box is usually sufficient in geometric applications. For an internal tree node, the distance returned must not be greater than the distance to any of the child nodes. If the returned distance is not exact, the function must set `*recheck` to true. (This is not necessary for internal tree nodes; for them, the calculation is always

assumed to be inexact.) In this case the executor will calculate the accurate distance after fetching the tuple from the heap, and reorder the tuples if necessary.

If the distance function returns `*recheck = true` for any leaf node, the original ordering operator's return type must be `float8` or `float4`, and the distance function's result values must be comparable to those of the original ordering operator, since the executor will sort using both distance function results and recalculated ordering-operator results. Otherwise, the distance function's result values can be any finite `float8` values, so long as the relative order of the result values matches the order returned by the ordering operator. (Infinity and minus infinity are used internally to handle cases such as nulls, so it is not recommended that distance functions return these values.)

#### `fetch`

Converts the compressed index representation of a data item into the original data type, for index-only scans. The returned data must be an exact, non-lossy copy of the originally indexed value.

The SQL declaration of the function must look like this:

```
CREATE OR REPLACE FUNCTION my_fetch(internal)
RETURNS internal
AS 'MODULE_PATHNAME'
LANGUAGE C STRICT;
```

The argument is a pointer to a `GISTENTRY` struct. On entry, its `key` field contains a non-NULL leaf datum in compressed form. The return value is another `GISTENTRY` struct, whose `key` field contains the same datum in its original, uncompressed form. If the opclass's compress function does nothing for leaf entries, the `fetch` method can return the argument as-is. Or, if the opclass does not have a compress function, the `fetch` method can be omitted as well, since it would necessarily be a no-op.

The matching code in the C module could then follow this skeleton:

```
PG_FUNCTION_INFO_V1(my_fetch);
```

```
Datum
my_fetch(PG_FUNCTION_ARGS)
{
    GISTENTRY *entry = (GISTENTRY *) PG_GETARG_POINTER(0);
    input_data_type *in = DatumGetPointer(entry->key);
    fetched_data_type *fetched_data;
    GISTENTRY *retval;

    retval = palloc(sizeof(GISTENTRY));
    fetched_data = palloc(sizeof(fetched_data_type));

    /*
     * Convert 'fetched_data' into the a Datum of the original datatype.
     */

    /* fill *retval from fetched_data. */
    gistentryinit(retval, PointerGetDatum(converted_datum),
                  entry->rel, entry->page, entry->offset, FALSE);

    PG_RETURN_POINTER(retval);
}
```

If the compress method is lossy for leaf entries, the operator class cannot support index-only scans, and must not define a `fetch` function.

#### `options`

Allows definition of user-visible parameters that control operator class behavior.

The SQL declaration of the function must look like this:

```
CREATE OR REPLACE FUNCTION my_options(internal)
RETURNS void
AS 'MODULE_PATHNAME'
LANGUAGE C STRICT;
```

The function is passed a pointer to a `local_relopts` struct, which needs to be filled with a set of operator class specific options. The options can be accessed from other support functions using the `PG_HAS_OPCLASS_OPTIONS()` and `PG_GET_OPCLASS_OPTIONS()` macros.

An example implementation of `my_options()` and parameters use from other support functions are given below:

```
typedef enum MyEnumType
{
    MY_ENUM_ON,
    MY_ENUM_OFF,
    MY_ENUM_AUTO
} MyEnumType;

typedef struct
{
    int32    vl_len_;    /* varlena header (do not touch directly!) */
    int      int_param; /* integer parameter */
    double   real_param; /* real parameter */
    MyEnumType enum_param; /* enum parameter */
    int      str_param; /* string parameter */
} MyOptionsStruct;

/* String representation of enum values */
static relopt_enum_elt_def myEnumValues[] =
{
    {"on", MY_ENUM_ON},
    {"off", MY_ENUM_OFF},
    {"auto", MY_ENUM_AUTO},
    {(const char *) NULL} /* list terminator */
};

static char *str_param_default = "default";

/*
 * Sample validator: checks that string is not longer than 8 bytes.
 */
static void
validate_my_string_relopt(const char *value)
{
    if (strlen(value) > 8)
        ereport(ERROR,
                (errcode(ERRCODE_INVALID_PARAMETER_VALUE),
                 errmsg("str_param must be at most 8 bytes")));
}

/*
 * Sample filler: switches characters to lower case.
 */
static Size
fill_my_string_relopt(const char *value, void *ptr)
{
    char    *tmp = str_tolower(value, strlen(value), DEFAULT_COLLATION_OID);
    int      len = strlen(tmp);
```

```
    if (ptr)
        strcpy((char *) ptr, tmp);

    pfree(tmp);
    return len + 1;
}

PG_FUNCTION_INFO_V1(my_options);

Datum
my_options(PG_FUNCTION_ARGS)
{
    local_relopts *relopts = (local_relopts *) PG_GETARG_POINTER(0);

    init_local_reloptions(relopts, sizeof(MyOptionsStruct));
    add_local_int_reloption(relopts, "int_param", "integer parameter",
                           100, 0, 1000000,
                           offsetof(MyOptionsStruct, int_param));
    add_local_real_reloption(relopts, "real_param", "real parameter",
                             1.0, 0.0, 1000000.0,
                             offsetof(MyOptionsStruct, real_param));
    add_local_enum_reloption(relopts, "enum_param", "enum parameter",
                             myEnumValues, MY_ENUM_ON,
                             "Valid values are: \"on\", \"off\" and \"auto\".",
                             offsetof(MyOptionsStruct, enum_param));
    add_local_string_reloption(relopts, "str_param", "string parameter",
                               str_param_default,
                               &validate_my_string_relopt,
                               &fill_my_string_relopt,
                               offsetof(MyOptionsStruct, str_param));

    PG_RETURN_VOID();
}

PG_FUNCTION_INFO_V1(my_compress);

Datum
my_compress(PG_FUNCTION_ARGS)
{
    int      int_param = 100;
    double   real_param = 1.0;
    MyEnumType enum_param = MY_ENUM_ON;
    char      *str_param = str_param_default;

    /*
     * Normally, when opclass contains 'options' method, then options are always
     * passed to support functions. However, if you add 'options' method to
     * existing opclass, previously defined indexes have no options, so the
     * check is required.
     */
    if (PG_HAS_OPCLASS_OPTIONS())
    {
        MyOptionsStruct *options = (MyOptionsStruct *) PG_GET_OPCLASS_OPTIONS();

        int_param = options->int_param;
        real_param = options->real_param;
        enum_param = options->enum_param;
    }
}
```

```
        str_param = GET_STRING_RELOPTION(options, str_param);
    }

    /* the rest implementation of support function */
}
```

Since the representation of the key in GiST is flexible, it may depend on user-specified parameters. For instance, the length of key signature may be specified. See `gtsvector_options()` for example.

#### `sortsupport`

Returns a comparator function to sort data in a way that preserves locality. It is used by `CREATE INDEX` and `REINDEX` commands. The quality of the created index depends on how well the sort order determined by the comparator function preserves locality of the inputs.

The `sortsupport` method is optional. If it is not provided, `CREATE INDEX` builds the index by inserting each tuple to the tree using the `penalty` and `picksplit` functions, which is much slower.

The SQL declaration of the function must look like this:

```
CREATE OR REPLACE FUNCTION my_sortsupport(internal)
RETURNS void
AS 'MODULE_PATHNAME'
LANGUAGE C STRICT;
```

The argument is a pointer to a `SortSupport` struct. At a minimum, the function must fill in its `comparator` field. The comparator takes three arguments: two `Datums` to compare, and a pointer to the `SortSupport` struct. The `Datums` are the two indexed values in the format that they are stored in the index; that is, in the format returned by the `compress` method. The full API is defined in [src/include/utils/sortsupport.h](#).

The matching code in the C module could then follow this skeleton:

```
PG_FUNCTION_INFO_V1(my_sortsupport);

static int
my_fastcmp(Datum x, Datum y, SortSupport ssup)
{
    /* establish order between x and y by computing some sorting value z */

    int z1 = ComputeSpatialCode(x);
    int z2 = ComputeSpatialCode(y);

    return z1 == z2 ? 0 : z1 > z2 ? 1 : -1;
}

Datum
my_sortsupport(PG_FUNCTION_ARGS)
{
    SortSupport ssup = (SortSupport) PG_GETARG_POINTER(0);

    ssup->comparator = my_fastcmp;
    PG_RETURN_VOID();
}
```

All the GiST support methods are normally called in short-lived memory contexts; that is, `CurrentMemoryContext` will get reset after each tuple is processed. It is therefore not very important to worry about `pfree`'ing everything you `palloc`. However, in some cases it's useful for a support method to cache data across repeated calls. To do that, allocate the longer-lived data in `fcinfo->flinfo->fn_mcxt`, and keep a pointer to it in `fcinfo->flinfo->fn_extra`. Such data will survive for the life of the index operation

(e.g., a single GiST index scan, index build, or index tuple insertion). Be careful to `pfree` the previous value when replacing a `fn_extra` value, or the leak will accumulate for the duration of the operation.

## 65.4. Implementation

### 65.4.1. GiST Index Build Methods

The simplest way to build a GiST index is just to insert all the entries, one by one. This tends to be slow for large indexes, because if the index tuples are scattered across the index and the index is large enough to not fit in cache, a lot of random I/O will be needed. PostgreSQL supports two alternative methods for initial build of a GiST index: *sorted* and *buffered* modes.

The sorted method is only available if each of the opclasses used by the index provides a `sortsupport` function, as described in [Section 65.3](#). If they do, this method is usually the best, so it is used by default.

The buffered method works by not inserting tuples directly into the index right away. It can dramatically reduce the amount of random I/O needed for non-ordered data sets. For well-ordered data sets the benefit is smaller or non-existent, because only a small number of pages receive new tuples at a time, and those pages fit in cache even if the index as a whole does not.

The buffered method needs to call the `penalty` function more often than the simple method does, which consumes some extra CPU resources. Also, the buffers need temporary disk space, up to the size of the resulting index. Buffering can also influence the quality of the resulting index, in both positive and negative directions. That influence depends on various factors, like the distribution of the input data and the operator class implementation.

If sorting is not possible, then by default a GiST index build switches to the buffering method when the index size reaches `effective_cache_size`. Buffering can be manually forced or prevented by the `buffering` parameter to the `CREATE INDEX` command. The default behavior is good for most cases, but turning buffering off might speed up the build somewhat if the input data is ordered.

## 65.5. Examples

The Postgres Pro core system currently provides text search support (indexing for `tsvector` and `tsquery`) as well as R-Tree equivalent functionality for some of the built-in geometric data types. The following `contrib` modules also contain GiST operator classes:

`btree_gist`

B-tree equivalent functionality for several data types

`cube`

Indexing for multidimensional cubes

`hstore`

Module for storing (key, value) pairs

`intarray`

RD-Tree for one-dimensional array of `int4` values

`ltree`

Indexing for tree-like structures

`pg_trgm`

Text similarity using trigram matching

`seg`

Indexing for “float ranges”

# Chapter 66. SP-GiST Indexes

## 66.1. Introduction

SP-GiST is an abbreviation for space-partitioned GiST. SP-GiST supports partitioned search trees, which facilitate development of a wide range of different non-balanced data structures, such as quad-trees, k-d trees, and radix trees (tries). The common feature of these structures is that they repeatedly divide the search space into partitions that need not be of equal size. Searches that are well matched to the partitioning rule can be very fast.

These popular data structures were originally developed for in-memory usage. In main memory, they are usually designed as a set of dynamically allocated nodes linked by pointers. This is not suitable for direct storing on disk, since these chains of pointers can be rather long which would require too many disk accesses. In contrast, disk-based data structures should have a high fanout to minimize I/O. The challenge addressed by SP-GiST is to map search tree nodes to disk pages in such a way that a search need access only a few disk pages, even if it traverses many nodes.

Like GiST, SP-GiST is meant to allow the development of custom data types with the appropriate access methods, by an expert in the domain of the data type, rather than a database expert.

Some of the information here is derived from Purdue University's SP-GiST Indexing Project [web site](#). The SP-GiST implementation in Postgres Pro is primarily maintained by Teodor Sigaev and Oleg Bartunov, and there is more information on their [web site](#).

## 66.2. Built-in Operator Classes

The core Postgres Pro distribution includes the SP-GiST operator classes shown in [Table 66.1](#).

**Table 66.1. Built-in SP-GiST Operator Classes**

| Name     | Indexable Operators | Ordering Operators |
|----------|---------------------|--------------------|
| box_ops  | << (box,box)        | <-> (box,point)    |
|          | &< (box,box)        |                    |
|          | &> (box,box)        |                    |
|          | >> (box,box)        |                    |
|          | <@ (box,box)        |                    |
|          | @> (box,box)        |                    |
|          | ~= (box,box)        |                    |
|          | && (box,box)        |                    |
|          | <<  (box,box)       |                    |
|          | &<  (box,box)       |                    |
|          | &> (box,box)        |                    |
|          | >> (box,box)        |                    |
|          |                     |                    |
| inet_ops | << (inet,inet)      |                    |
|          | <<= (inet,inet)     |                    |
|          | >> (inet,inet)      |                    |
|          | >>= (inet,inet)     |                    |
|          | = (inet,inet)       |                    |
|          | <> (inet,inet)      |                    |
|          | < (inet,inet)       |                    |
|          | <= (inet,inet)      |                    |

| Name           | Indexable Operators      | Ordering Operators  |
|----------------|--------------------------|---------------------|
|                | > (inet,inet)            |                     |
|                | >= (inet,inet)           |                     |
|                | && (inet,inet)           |                     |
| kd_point_ops   | >> (point,point)         | <-> (point,point)   |
|                | << (point,point)         |                     |
|                | >> (point,point)         |                     |
|                | <<  (point,point)        |                     |
|                | ~= (point,point)         |                     |
|                | <@ (point,box)           |                     |
| poly_ops       | << (polygon,polygon)     | <-> (polygon,point) |
|                | &< (polygon,polygon)     |                     |
|                | &> (polygon,polygon)     |                     |
|                | >> (polygon,polygon)     |                     |
|                | <@ (polygon,polygon)     |                     |
|                | @> (polygon,polygon)     |                     |
|                | ~= (polygon,polygon)     |                     |
|                | && (polygon,polygon)     |                     |
|                | <<  (polygon,polygon)    |                     |
|                | &<  (polygon,polygon)    |                     |
|                | >> (polygon,polygon)     |                     |
|                | &> (polygon,polygon)     |                     |
| quad_point_ops | >> (point,point)         | <-> (point,point)   |
|                | << (point,point)         |                     |
|                | >> (point,point)         |                     |
|                | <<  (point,point)        |                     |
|                | ~= (point,point)         |                     |
|                | <@ (point,box)           |                     |
| range_ops      | = (anyrange,anyrange)    |                     |
|                | && (anyrange,anyrange)   |                     |
|                | @> (anyrange,anyelement) |                     |
|                | @> (anyrange,anyrange)   |                     |
|                | <@ (anyrange,anyrange)   |                     |
|                | << (anyrange,anyrange)   |                     |
|                | >> (anyrange,anyrange)   |                     |
|                | &< (anyrange,anyrange)   |                     |
|                | &> (anyrange,anyrange)   |                     |
|                | - - (anyrange,anyrange)  |                     |
| text_ops       | = (text,text)            |                     |
|                | < (text,text)            |                     |
|                | <= (text,text)           |                     |

| Name | Indexable Operators | Ordering Operators |
|------|---------------------|--------------------|
|      | > (text, text)      |                    |
|      | >= (text, text)     |                    |
|      | ~<~ (text, text)    |                    |
|      | ~<=~ (text, text)   |                    |
|      | ~>=~ (text, text)   |                    |
|      | ~>~ (text, text)    |                    |
|      | ^@ (text, text)     |                    |

Of the two operator classes for type `point`, `quad_point_ops` is the default. `kd_point_ops` supports the same operators but uses a different index data structure that may offer better performance in some applications.

The `quad_point_ops`, `kd_point_ops` and `poly_ops` operator classes support the `<->` ordering operator, which enables the k-nearest neighbor (k-NN) search over indexed point or polygon data sets.

## 66.3. Extensibility

SP-GiST offers an interface with a high level of abstraction, requiring the access method developer to implement only methods specific to a given data type. The SP-GiST core is responsible for efficient disk mapping and searching the tree structure. It also takes care of concurrency and logging considerations.

Leaf tuples of an SP-GiST tree usually contain values of the same data type as the indexed column, although it is also possible for them to contain lossy representations of the indexed column. Leaf tuples stored at the root level will directly represent the original indexed data value, but leaf tuples at lower levels might contain only a partial value, such as a suffix. In that case the operator class support functions must be able to reconstruct the original value using information accumulated from the inner tuples that are passed through to reach the leaf level.

When an SP-GiST index is created with `INCLUDE` columns, the values of those columns are also stored in leaf tuples. The `INCLUDE` columns are of no concern to the SP-GiST operator class, so they are not discussed further here.

Inner tuples are more complex, since they are branching points in the search tree. Each inner tuple contains a set of one or more *nodes*, which represent groups of similar leaf values. A node contains a downlink that leads either to another, lower-level inner tuple, or to a short list of leaf tuples that all lie on the same index page. Each node normally has a *label* that describes it; for example, in a radix tree the node label could be the next character of the string value. (Alternatively, an operator class can omit the node labels, if it works with a fixed set of nodes for all inner tuples; see [Section 66.4.2](#).) Optionally, an inner tuple can have a *prefix* value that describes all its members. In a radix tree this could be the common prefix of the represented strings. The prefix value is not necessarily really a prefix, but can be any data needed by the operator class; for example, in a quad-tree it can store the central point that the four quadrants are measured with respect to. A quad-tree inner tuple would then also contain four nodes corresponding to the quadrants around this central point.

Some tree algorithms require knowledge of level (or depth) of the current tuple, so the SP-GiST core provides the possibility for operator classes to manage level counting while descending the tree. There is also support for incrementally reconstructing the represented value when that is needed, and for passing down additional data (called *traverse values*) during a tree descent.

### Note

The SP-GiST core code takes care of null entries. Although SP-GiST indexes do store entries for nulls in indexed columns, this is hidden from the index operator class code: no null index entries or search conditions will ever be passed to the operator class methods. (It is assumed that SP-

GiST operators are strict and so cannot succeed for null values.) Null values are therefore not discussed further here.

There are five user-defined methods that an index operator class for SP-GiST must provide, and two are optional. All five mandatory methods follow the convention of accepting two `internal` arguments, the first of which is a pointer to a C struct containing input values for the support method, while the second argument is a pointer to a C struct where output values must be placed. Four of the mandatory methods just return `void`, since all their results appear in the output struct; but `leaf_consistent` returns a `boolean` result. The methods must not modify any fields of their input structs. In all cases, the output struct is initialized to zeroes before calling the user-defined method. The optional sixth method `compress` accepts a `datum` to be indexed as the only argument and returns a value suitable for physical storage in a leaf tuple. The optional seventh method `options` accepts an `internal` pointer to a C struct, where opclass-specific parameters should be placed, and returns `void`.

The five mandatory user-defined methods are:

`config`

Returns static information about the index implementation, including the data type OIDs of the prefix and node label data types.

The SQL declaration of the function must look like this:

```
CREATE FUNCTION my_config(internal, internal) RETURNS void ...
```

The first argument is a pointer to a `spgConfigIn` C struct, containing input data for the function. The second argument is a pointer to a `spgConfigOut` C struct, which the function must fill with result data.

```
typedef struct spgConfigIn
{
    Oid      attType;          /* Data type to be indexed */
} spgConfigIn;

typedef struct spgConfigOut
{
    Oid      prefixType;       /* Data type of inner-tuple prefixes */
    Oid      labelType;        /* Data type of inner-tuple node labels */
    Oid      leafType;         /* Data type of leaf-tuple values */
    bool     canReturnData;    /* Opclass can reconstruct original data */
    bool     longValuesOK;     /* Opclass can cope with values > 1 page */
} spgConfigOut;
```

`attType` is passed in order to support polymorphic index operator classes; for ordinary fixed-data-type operator classes, it will always have the same value and so can be ignored.

For operator classes that do not use prefixes, `prefixType` can be set to `VOIDOID`. Likewise, for operator classes that do not use node labels, `labelType` can be set to `VOIDOID`. `canReturnData` should be set true if the operator class is capable of reconstructing the originally-supplied index value. `longValuesOK` should be set true only when the `attType` is of variable length and the operator class is capable of segmenting long values by repeated suffixing (see [Section 66.4.1](#)).

`leafType` should match the index storage type defined by the operator class's `opkeytype` catalog entry. (Note that `opkeytype` can be zero, implying the storage type is the same as the operator class's input type, which is the most common situation.) For reasons of backward compatibility, the `config` method can set `leafType` to some other value, and that value will be used; but this is deprecated since the index contents are then incorrectly identified in the catalogs. Also, it's permissible to leave `leafType` uninitialized (zero); that is interpreted as meaning the index storage type derived from `opkeytype`.

When `attType` and `leafType` are different, the optional method `compress` must be provided. Method `compress` is responsible for transformation of datums to be indexed from `attType` to `leafType`.

choose

Chooses a method for inserting a new value into an inner tuple.

The SQL declaration of the function must look like this:

```
CREATE FUNCTION my_choose(internal, internal) RETURNS void ...
```

The first argument is a pointer to a `spgChooseIn` C struct, containing input data for the function. The second argument is a pointer to a `spgChooseOut` C struct, which the function must fill with result data.

```
typedef struct spgChooseIn
{
    Datum        datum;           /* original datum to be indexed */
    Datum        leafDatum;       /* current datum to be stored at leaf */
    int          level;           /* current level (counting from zero) */

    /* Data from current inner tuple */
    bool         allTheSame;      /* tuple is marked all-the-same? */
    bool         hasPrefix;       /* tuple has a prefix? */
    Datum        prefixDatum;     /* if so, the prefix value */
    int          nNodes;          /* number of nodes in the inner tuple */
    Datum        *nodeLabels;     /* node label values (NULL if none) */
} spgChooseIn;

typedef enum spgChooseResultType
{
    spgMatchNode = 1,            /* descend into existing node */
    spgAddNode,                  /* add a node to the inner tuple */
    spgSplitTuple                /* split inner tuple (change its prefix) */
} spgChooseResultType;

typedef struct spgChooseOut
{
    spgChooseResultType resultType; /* action code, see above */
    union
    {
        struct /* results for spgMatchNode */
        {
            int      nodeN;        /* descend to this node (index from 0) */
            int      levelAdd;     /* increment level by this much */
            Datum     restDatum;    /* new leaf datum */
        } matchNode;
        struct /* results for spgAddNode */
        {
            Datum     nodeLabel;    /* new node's label */
            int       nodeN;        /* where to insert it (index from 0) */
        } addNode;
        struct /* results for spgSplitTuple */
        {
            /* Info to form new upper-level inner tuple with one child tuple */
            bool      prefixHasPrefix; /* tuple should have a prefix? */
            Datum     prefixPrefixDatum; /* if so, its value */
            int       prefixNNodes;    /* number of nodes */
            Datum     *prefixNodeLabels; /* their labels (or NULL for
                                         * no labels) */
            int       childNodeN;     /* which node gets child tuple */

            /* Info to form new lower-level inner tuple with all old nodes */
            bool      postfixHasPrefix; /* tuple should have a prefix? */
        }
    }
}
```

```

        Datum      postfixPrefixDatum; /* if so, its value */
    }              splitTuple;
}                  result;
} spgChooseOut;

```

`datum` is the original datum of `spgConfigIn.attType` type that was to be inserted into the index. `leafDatum` is a value of `spgConfigOut.leafType` type, which is initially a result of method `compress` applied to `datum` when method `compress` is provided, or the same value as `datum` otherwise. `leafDatum` can change at lower levels of the tree if the `choose` or `picksplit` methods change it. When the insertion search reaches a leaf page, the current value of `leafDatum` is what will be stored in the newly created leaf tuple. `level` is the current inner tuple's level, starting at zero for the root level. `allTheSame` is true if the current inner tuple is marked as containing multiple equivalent nodes (see [Section 66.4.3](#)). `hasPrefix` is true if the current inner tuple contains a prefix; if so, `prefixDatum` is its value. `nNodes` is the number of child nodes contained in the inner tuple, and `nodeLabels` is an array of their label values, or NULL if there are no labels.

The `choose` function can determine either that the new value matches one of the existing child nodes, or that a new child node must be added, or that the new value is inconsistent with the tuple prefix and so the inner tuple must be split to create a less restrictive prefix.

If the new value matches one of the existing child nodes, set `resultType` to `spgMatchNode`. Set `nodeN` to the index (from zero) of that node in the node array. Set `levelAdd` to the increment in `level` caused by descending through that node, or leave it as zero if the operator class does not use levels. Set `restDatum` to equal `leafDatum` if the operator class does not modify datums from one level to the next, or otherwise set it to the modified value to be used as `leafDatum` at the next level.

If a new child node must be added, set `resultType` to `spgAddNode`. Set `nodeLabel` to the label to be used for the new node, and set `nodeN` to the index (from zero) at which to insert the node in the node array. After the node has been added, the `choose` function will be called again with the modified inner tuple; that call should result in an `spgMatchNode` result.

If the new value is inconsistent with the tuple prefix, set `resultType` to `spgSplitTuple`. This action moves all the existing nodes into a new lower-level inner tuple, and replaces the existing inner tuple with a tuple having a single downlink pointing to the new lower-level inner tuple. Set `prefixHasPrefix` to indicate whether the new upper tuple should have a prefix, and if so set `prefixPrefixDatum` to the prefix value. This new prefix value must be sufficiently less restrictive than the original to accept the new value to be indexed. Set `prefixNNodes` to the number of nodes needed in the new tuple, and set `prefixNodeLabels` to a palloc'd array holding their labels, or to NULL if node labels are not required. Note that the total size of the new upper tuple must be no more than the total size of the tuple it is replacing; this constrains the lengths of the new prefix and new labels. Set `childNodeN` to the index (from zero) of the node that will downlink to the new lower-level inner tuple. Set `postfixHasPrefix` to indicate whether the new lower-level inner tuple should have a prefix, and if so set `postfixPrefixDatum` to the prefix value. The combination of these two prefixes and the downlink node's label (if any) must have the same meaning as the original prefix, because there is no opportunity to alter the node labels that are moved to the new lower-level tuple, nor to change any child index entries. After the node has been split, the `choose` function will be called again with the replacement inner tuple. That call may return an `spgAddNode` result, if no suitable node was created by the `spgSplitTuple` action. Eventually `choose` must return `spgMatchNode` to allow the insertion to descend to the next level.

#### `picksplit`

Decides how to create a new inner tuple over a set of leaf tuples.

The SQL declaration of the function must look like this:

```
CREATE FUNCTION my_picksplit(internal, internal) RETURNS void ...
```

The first argument is a pointer to a `spgPickSplitIn` C struct, containing input data for the function. The second argument is a pointer to a `spgPickSplitOut` C struct, which the function must fill with result data.

```

typedef struct spgPickSplitIn
{
    int          nTuples;          /* number of leaf tuples */
    Datum        *datums;          /* their datums (array of length nTuples) */
    int          level;            /* current level (counting from zero) */
} spgPickSplitIn;

typedef struct spgPickSplitOut
{
    bool          hasPrefix;        /* new inner tuple should have a prefix? */
    Datum         prefixDatum;      /* if so, its value */

    int           nNodes;           /* number of nodes for new inner tuple */
    Datum         *nodeLabels;      /* their labels (or NULL for no labels) */

    int           *mapTuplesToNodes; /* node index for each leaf tuple */
    Datum         *leafTupleDatums; /* datum to store in each new leaf tuple */
} spgPickSplitOut;

```

`nTuples` is the number of leaf tuples provided. `datums` is an array of their datum values of `spgConfigOut.leafType` type. `level` is the current level that all the leaf tuples share, which will become the level of the new inner tuple.

Set `hasPrefix` to indicate whether the new inner tuple should have a prefix, and if so set `prefixDatum` to the prefix value. Set `nNodes` to indicate the number of nodes that the new inner tuple will contain, and set `nodeLabels` to an array of their label values, or to NULL if node labels are not required. Set `mapTuplesToNodes` to an array that gives the index (from zero) of the node that each leaf tuple should be assigned to. Set `leafTupleDatums` to an array of the values to be stored in the new leaf tuples (these will be the same as the input `datums` if the operator class does not modify datums from one level to the next). Note that the `picksplit` function is responsible for `palloc`'ing the `nodeLabels`, `mapTuplesToNodes` and `leafTupleDatums` arrays.

If more than one leaf tuple is supplied, it is expected that the `picksplit` function will classify them into more than one node; otherwise it is not possible to split the leaf tuples across multiple pages, which is the ultimate purpose of this operation. Therefore, if the `picksplit` function ends up placing all the leaf tuples in the same node, the core SP-GiST code will override that decision and generate an inner tuple in which the leaf tuples are assigned at random to several identically-labeled nodes. Such a tuple is marked `allTheSame` to signify that this has happened. The `choose` and `inner_consistent` functions must take suitable care with such inner tuples. See [Section 66.4.3](#) for more information.

`picksplit` can be applied to a single leaf tuple only in the case that the `config` function set `long-ValuesOK` to true and a larger-than-a-page input value has been supplied. In this case the point of the operation is to strip off a prefix and produce a new, shorter leaf datum value. The call will be repeated until a leaf datum short enough to fit on a page has been produced. See [Section 66.4.1](#) for more information.

`inner_consistent`

Returns set of nodes (branches) to follow during tree search.

The SQL declaration of the function must look like this:

```
CREATE FUNCTION my_inner_consistent(internal, internal) RETURNS void ...
```

The first argument is a pointer to a `spgInnerConsistentIn` C struct, containing input data for the function. The second argument is a pointer to a `spgInnerConsistentOut` C struct, which the function must fill with result data.

```

typedef struct spgInnerConsistentIn
{
    ScanKey      scankeys;          /* array of operators and comparison values */

```

```

ScanKey      orderby;          /* array of ordering operators and comparison
                                * values */
int          nkeys;           /* length of scankeys array */
int          norderby;        /* length of orderby array */

Datum        reconstructedValue; /* value reconstructed at parent */
void         *traversalValue; /* opclass-specific traverse value */
MemoryContext traversalMemoryContext; /* put new traverse values here */
int          level;           /* current level (counting from zero) */
bool         returnData;      /* original data must be returned? */

/* Data from current inner tuple */
bool         allTheSame;      /* tuple is marked all-the-same? */
bool         hasPrefix;       /* tuple has a prefix? */
Datum        prefixDatum;     /* if so, the prefix value */
int          nNodes;          /* number of nodes in the inner tuple */
Datum        *nodeLabels;     /* node label values (NULL if none) */
} spgInnerConsistentIn;

typedef struct spgInnerConsistentOut
{
    int          nNodes;          /* number of child nodes to be visited */
    int          *nodeNumbers;     /* their indexes in the node array */
    int          *levelAdds;       /* increment level by this much for each */
    Datum        *reconstructedValues; /* associated reconstructed values */
    void         **traversalValues; /* opclass-specific traverse values */
    double       *distances;       /* associated distances */
} spgInnerConsistentOut;

```

The array `scankeys`, of length `nkeys`, describes the index search condition(s). These conditions are combined with AND — only index entries that satisfy all of them are interesting. (Note that `nkeys = 0` implies that all index entries satisfy the query.) Usually the consistent function only cares about the `sk_strategy` and `sk_argument` fields of each array entry, which respectively give the indexable operator and comparison value. In particular it is not necessary to check `sk_flags` to see if the comparison value is NULL, because the SP-GiST core code will filter out such conditions. The array `orderby`, of length `norderby`, describes ordering operators (if any) in the same manner. `reconstructedValue` is the value reconstructed for the parent tuple; it is (Datum) 0 at the root level or if the `inner_consistent` function did not provide a value at the parent level. `traversalValue` is a pointer to any traverse data passed down from the previous call of `inner_consistent` on the parent index tuple, or NULL at the root level. `traversalMemoryContext` is the memory context in which to store output traverse values (see below). `level` is the current inner tuple's level, starting at zero for the root level. `returnData` is true if reconstructed data is required for this query; this will only be so if the `config` function asserted `canReturnData`. `allTheSame` is true if the current inner tuple is marked “all-the-same”; in this case all the nodes have the same label (if any) and so either all or none of them match the query (see [Section 66.4.3](#)). `hasPrefix` is true if the current inner tuple contains a prefix; if so, `prefixDatum` is its value. `nNodes` is the number of child nodes contained in the inner tuple, and `nodeLabels` is an array of their label values, or NULL if the nodes do not have labels.

`nNodes` must be set to the number of child nodes that need to be visited by the search, and `nodeNumbers` must be set to an array of their indexes. If the operator class keeps track of levels, set `levelAdds` to an array of the level increments required when descending to each node to be visited. (Often these increments will be the same for all the nodes, but that's not necessarily so, so an array is used.) If value reconstruction is needed, set `reconstructedValues` to an array of the values reconstructed for each child node to be visited; otherwise, leave `reconstructedValues` as NULL. The reconstructed values are assumed to be of type `spgConfigOut.leafType`. (However, since the core system will do nothing with them except possibly copy them, it is sufficient for them to have the same `typlen` and `typbyval` properties as `leafType`.) If ordered search is performed, set `distances` to an array of distance values according to `orderby` array (nodes with lowest distances will be processed first).

Leave it NULL otherwise. If it is desired to pass down additional out-of-band information (“traverse values”) to lower levels of the tree search, set `traversalValues` to an array of the appropriate traverse values, one for each child node to be visited; otherwise, leave `traversalValues` as NULL. Note that the `inner_consistent` function is responsible for `malloc`'ing the `nodeNumbers`, `levelAdds`, `distances`, `reconstructedValues`, and `traversalValues` arrays in the current memory context. However, any output traverse values pointed to by the `traversalValues` array should be allocated in `traversalMemoryContext`. Each traverse value must be a single `malloc`'d chunk.

`leaf_consistent`

Returns true if a leaf tuple satisfies a query.

The SQL declaration of the function must look like this:

```
CREATE FUNCTION my_leaf_consistent(internal, internal) RETURNS bool ...
```

The first argument is a pointer to a `spgLeafConsistentIn` C struct, containing input data for the function. The second argument is a pointer to a `spgLeafConsistentOut` C struct, which the function must fill with result data.

```
typedef struct spgLeafConsistentIn
{
    ScanKey      scankeys;          /* array of operators and comparison values */
    ScanKey      orderbys;          /* array of ordering operators and comparison
                                     * values */
    int          nkeys;             /* length of scankeys array */
    int          norderbys;         /* length of orderbys array */

    Datum        reconstructedValue; /* value reconstructed at parent */
    void         *traversalValue;    /* opclass-specific traverse value */
    int          level;             /* current level (counting from zero) */
    bool         returnData;        /* original data must be returned? */

    Datum        leafDatum;         /* datum in leaf tuple */
} spgLeafConsistentIn;

typedef struct spgLeafConsistentOut
{
    Datum        leafValue;         /* reconstructed original data, if any */
    bool         recheck;           /* set true if operator must be rechecked */
    bool         recheckDistances; /* set true if distances must be rechecked */
    double       *distances;        /* associated distances */
} spgLeafConsistentOut;
```

The array `scankeys`, of length `nkeys`, describes the index search condition(s). These conditions are combined with AND — only index entries that satisfy all of them satisfy the query. (Note that `nkeys = 0` implies that all index entries satisfy the query.) Usually the consistent function only cares about the `sk_strategy` and `sk_argument` fields of each array entry, which respectively give the indexable operator and comparison value. In particular it is not necessary to check `sk_flags` to see if the comparison value is NULL, because the SP-GiST core code will filter out such conditions. The array `orderbys`, of length `norderbys`, describes the ordering operators in the same manner. `reconstructedValue` is the value reconstructed for the parent tuple; it is (Datum) 0 at the root level or if the `inner_consistent` function did not provide a value at the parent level. `traversalValue` is a pointer to any traverse data passed down from the previous call of `inner_consistent` on the parent index tuple, or NULL at the root level. `level` is the current leaf tuple's level, starting at zero for the root level. `returnData` is true if reconstructed data is required for this query; this will only be so if the `config` function asserted `canReturnData`. `leafDatum` is the key value of `spgConfigOut.leafType` stored in the current leaf tuple.

The function must return true if the leaf tuple matches the query, or false if not. In the true case, if `returnData` is true then `leafValue` must be set to the value (of type `spgConfigIn.attType`) originally

supplied to be indexed for this leaf tuple. Also, `recheck` may be set to `true` if the match is uncertain and so the operator(s) must be re-applied to the actual heap tuple to verify the match. If ordered search is performed, set `distances` to an array of distance values according to `orderbys` array. Leave it `NULL` otherwise. If at least one of returned distances is not exact, set `recheckDistances` to `true`. In this case, the executor will calculate the exact distances after fetching the tuple from the heap, and will reorder the tuples if needed.

The optional user-defined methods are:

`Datum compress(Datum in)`

Converts a data item into a format suitable for physical storage in a leaf tuple of the index. It accepts a value of type `spgConfigIn.attType` and returns a value of type `spgConfigOut.leafType`. The output value must not contain an out-of-line TOAST pointer.

Note: the `compress` method is only applied to values to be stored. The consistent methods receive query `scankeys` unchanged, without transformation using `compress`.

`options`

Defines a set of user-visible parameters that control operator class behavior.

The SQL declaration of the function must look like this:

```
CREATE OR REPLACE FUNCTION my_options(internal)
RETURNS void
AS 'MODULE_PATHNAME'
LANGUAGE C STRICT;
```

The function is passed a pointer to a `local_relopts` struct, which needs to be filled with a set of operator class specific options. The options can be accessed from other support functions using the `PG_HAS_OPCLASS_OPTIONS()` and `PG_GET_OPCLASS_OPTIONS()` macros.

Since the representation of the key in SP-GiST is flexible, it may depend on user-specified parameters.

All the SP-GiST support methods are normally called in a short-lived memory context; that is, `CurrentMemoryContext` will be reset after processing of each tuple. It is therefore not very important to worry about `pfree`'ing everything you `palloc`. (The `config` method is an exception: it should try to avoid leaking memory. But usually the `config` method need do nothing but assign constants into the passed parameter struct.)

If the indexed column is of a collatable data type, the index collation will be passed to all the support methods, using the standard `PG_GET_COLLATION()` mechanism.

## 66.4. Implementation

This section covers implementation details and other tricks that are useful for implementers of SP-GiST operator classes to know.

### 66.4.1. SP-GiST Limits

Individual leaf tuples and inner tuples must fit on a single index page (8kB by default). Therefore, when indexing values of variable-length data types, long values can only be supported by methods such as radix trees, in which each level of the tree includes a prefix that is short enough to fit on a page, and the final leaf level includes a suffix also short enough to fit on a page. The operator class should set `longValuesOK` to `true` only if it is prepared to arrange for this to happen. Otherwise, the SP-GiST core will reject any request to index a value that is too large to fit on an index page.

Likewise, it is the operator class's responsibility that inner tuples do not grow too large to fit on an index page; this limits the number of child nodes that can be used in one inner tuple, as well as the maximum size of a prefix value.

Another limitation is that when an inner tuple's node points to a set of leaf tuples, those tuples must all be in the same index page. (This is a design decision to reduce seeking and save space in the links that chain such tuples together.) If the set of leaf tuples grows too large for a page, a split is performed and an intermediate inner tuple is inserted. For this to fix the problem, the new inner tuple *must* divide the set of leaf values into more than one node group. If the operator class's `picksplit` function fails to do that, the SP-GiST core resorts to extraordinary measures described in [Section 66.4.3](#).

When `longValuesOK` is true, it is expected that successive levels of the SP-GiST tree will absorb more and more information into the prefixes and node labels of the inner tuples, making the required leaf datum smaller and smaller, so that eventually it will fit on a page. To prevent bugs in operator classes from causing infinite insertion loops, the SP-GiST core will raise an error if the leaf datum does not become any smaller within ten cycles of `choose` method calls.

### 66.4.2. SP-GiST Without Node Labels

Some tree algorithms use a fixed set of nodes for each inner tuple; for example, in a quad-tree there are always exactly four nodes corresponding to the four quadrants around the inner tuple's centroid point. In such a case the code typically works with the nodes by number, and there is no need for explicit node labels. To suppress node labels (and thereby save some space), the `picksplit` function can return NULL for the `nodeLabels` array, and likewise the `choose` function can return NULL for the `prefixNodeLabels` array during a `spgSplitTuple` action. This will in turn result in `nodeLabels` being NULL during subsequent calls to `choose` and `inner_consistent`. In principle, node labels could be used for some inner tuples and omitted for others in the same index.

When working with an inner tuple having unlabeled nodes, it is an error for `choose` to return `spgAddNode`, since the set of nodes is supposed to be fixed in such cases.

### 66.4.3. “All-the-Same” Inner Tuples

The SP-GiST core can override the results of the operator class's `picksplit` function when `picksplit` fails to divide the supplied leaf values into at least two node categories. When this happens, the new inner tuple is created with multiple nodes that each have the same label (if any) that `picksplit` gave to the one node it did use, and the leaf values are divided at random among these equivalent nodes. The `allTheSame` flag is set on the inner tuple to warn the `choose` and `inner_consistent` functions that the tuple does not have the node set that they might otherwise expect.

When dealing with an `allTheSame` tuple, a `choose` result of `spgMatchNode` is interpreted to mean that the new value can be assigned to any of the equivalent nodes; the core code will ignore the supplied `nodeN` value and descend into one of the nodes at random (so as to keep the tree balanced). It is an error for `choose` to return `spgAddNode`, since that would make the nodes not all equivalent; the `spgSplitTuple` action must be used if the value to be inserted doesn't match the existing nodes.

When dealing with an `allTheSame` tuple, the `inner_consistent` function should return either all or none of the nodes as targets for continuing the index search, since they are all equivalent. This may or may not require any special-case code, depending on how much the `inner_consistent` function normally assumes about the meaning of the nodes.

---

# Chapter 67. GIN Indexes

## 67.1. Introduction

GIN stands for Generalized Inverted Index. GIN is designed for handling cases where the items to be indexed are composite values, and the queries to be handled by the index need to search for element values that appear within the composite items. For example, the items could be documents, and the queries could be searches for documents containing specific words.

We use the word *item* to refer to a composite value that is to be indexed, and the word *key* to refer to an element value. GIN always stores and searches for keys, not item values per se.

A GIN index stores a set of (key, posting list) pairs, where a *posting list* is a set of row IDs in which the key occurs. The same row ID can appear in multiple posting lists, since an item can contain more than one key. Each key value is stored only once, so a GIN index is very compact for cases where the same key appears many times.

GIN is generalized in the sense that the GIN access method code does not need to know the specific operations that it accelerates. Instead, it uses custom strategies defined for particular data types. The strategy defines how keys are extracted from indexed items and query conditions, and how to determine whether a row that contains some of the key values in a query actually satisfies the query.

One advantage of GIN is that it allows the development of custom data types with the appropriate access methods, by an expert in the domain of the data type, rather than a database expert. This is much the same advantage as using GiST.

The GIN implementation in Postgres Pro is primarily maintained by Teodor Sigaev and Oleg Bartunov. There is more information about GIN on their [website](#).

## 67.2. Built-in Operator Classes

The core Postgres Pro distribution includes the GIN operator classes shown in [Table 67.1](#). (Some of the optional modules described in [Appendix F](#) provide additional GIN operator classes.)

**Table 67.1. Built-in GIN Operator Classes**

| Name           | Indexable Operators     |
|----------------|-------------------------|
| array_ops      | && (anyarray, anyarray) |
|                | @> (anyarray, anyarray) |
|                | <@ (anyarray, anyarray) |
|                | = (anyarray, anyarray)  |
| jsonb_ops      | @> (jsonb, jsonb)       |
|                | @? (jsonb, jsonpath)    |
|                | @@ (jsonb, jsonpath)    |
|                | ? (jsonb, text)         |
|                | ?  (jsonb, text[])      |
|                | ?& (jsonb, text[])      |
| jsonb_path_ops | @> (jsonb, jsonb)       |
|                | @? (jsonb, jsonpath)    |
|                | @@ (jsonb, jsonpath)    |
| tsvector_ops   | @@ (tsvector, tsquery)  |

| Name | Indexable Operators     |
|------|-------------------------|
|      | @@@ (tsvector, tsquery) |

Of the two operator classes for type `jsonb`, `jsonb_ops` is the default. `jsonb_path_ops` supports fewer operators but offers better performance for those operators. See [Section 8.14.4](#) for details.

## 67.3. Extensibility

The GIN interface has a high level of abstraction, requiring the access method implementer only to implement the semantics of the data type being accessed. The GIN layer itself takes care of concurrency, logging and searching the tree structure.

All it takes to get a GIN access method working is to implement a few user-defined methods, which define the behavior of keys in the tree and the relationships between keys, indexed items, and indexable queries. In short, GIN combines extensibility with generality, code reuse, and a clean interface.

There are two methods that an operator class for GIN must provide:

```
Datum *extractValue(Datum itemValue, int32 *nkeys, bool **nullFlags)
```

Returns a palloc'd array of keys given an item to be indexed. The number of returned keys must be stored into `*nkeys`. If any of the keys can be null, also palloc an array of `*nkeys` `bool` fields, store its address at `*nullFlags`, and set these null flags as needed. `*nullFlags` can be left `NULL` (its initial value) if all keys are non-null. The return value can be `NULL` if the item contains no keys.

```
Datum *extractQuery(Datum query, int32 *nkeys, StrategyNumber n, bool **pmatch, Pointer
**extra_data, bool **nullFlags, int32 *searchMode)
```

Returns a palloc'd array of keys given a value to be queried; that is, `query` is the value on the right-hand side of an indexable operator whose left-hand side is the indexed column. `n` is the strategy number of the operator within the operator class (see [Section 40.16.2](#)). Often, `extractQuery` will need to consult `n` to determine the data type of `query` and the method it should use to extract key values. The number of returned keys must be stored into `*nkeys`. If any of the keys can be null, also palloc an array of `*nkeys` `bool` fields, store its address at `*nullFlags`, and set these null flags as needed. `*nullFlags` can be left `NULL` (its initial value) if all keys are non-null. The return value can be `NULL` if the query contains no keys.

`searchMode` is an output argument that allows `extractQuery` to specify details about how the search will be done. If `*searchMode` is set to `GIN_SEARCH_MODE_DEFAULT` (which is the value it is initialized to before call), only items that match at least one of the returned keys are considered candidate matches. If `*searchMode` is set to `GIN_SEARCH_MODE_INCLUDE_EMPTY`, then in addition to items containing at least one matching key, items that contain no keys at all are considered candidate matches. (This mode is useful for implementing is-subset-of operators, for example.) If `*searchMode` is set to `GIN_SEARCH_MODE_ALL`, then all non-null items in the index are considered candidate matches, whether they match any of the returned keys or not. (This mode is much slower than the other two choices, since it requires scanning essentially the entire index, but it may be necessary to implement corner cases correctly. An operator that needs this mode in most cases is probably not a good candidate for a GIN operator class.) The symbols to use for setting this mode are defined in `access/gin.h`.

`pmatch` is an output argument for use when partial match is supported. To use it, `extractQuery` must allocate an array of `*nkeys` `bool`s and store its address at `*pmatch`. Each element of the array should be set to true if the corresponding key requires partial match, false if not. If `*pmatch` is set to `NULL` then GIN assumes partial match is not required. The variable is initialized to `NULL` before call, so this argument can simply be ignored by operator classes that do not support partial match.

`extra_data` is an output argument that allows `extractQuery` to pass additional data to the `consistent` and `comparePartial` methods. To use it, `extractQuery` must allocate an array of `*nkeys` pointers and store its address at `*extra_data`, then store whatever it wants to into the individual pointers.

The variable is initialized to `NULL` before call, so this argument can simply be ignored by operator classes that do not require extra data. If `*extra_data` is set, the whole array is passed to the `consistent` method, and the appropriate element to the `comparePartial` method.

An operator class must also provide a function to check if an indexed item matches the query. It comes in two flavors, a Boolean `consistent` function, and a ternary `triConsistent` function. `triConsistent` covers the functionality of both, so providing `triConsistent` alone is sufficient. However, if the Boolean variant is significantly cheaper to calculate, it can be advantageous to provide both. If only the Boolean variant is provided, some optimizations that depend on refuting index items before fetching all the keys are disabled.

```
bool consistent(bool check[], StrategyNumber n, Datum query, int32 nkeys, Pointer extra_data[], bool *recheck, Datum queryKeys[], bool nullFlags[])
```

Returns true if an indexed item satisfies the query operator with strategy number `n` (or might satisfy it, if the `recheck` indication is returned). This function does not have direct access to the indexed item's value, since GIN does not store items explicitly. Rather, what is available is knowledge about which key values extracted from the query appear in a given indexed item. The `check` array has length `nkeys`, which is the same as the number of keys previously returned by `extractQuery` for this query datum. Each element of the `check` array is true if the indexed item contains the corresponding query key, i.e., if (`check[i] == true`) the `i`-th key of the `extractQuery` result array is present in the indexed item. The original query datum is passed in case the `consistent` method needs to consult it, and so are the `queryKeys[]` and `nullFlags[]` arrays previously returned by `extractQuery`. `extra_data` is the extra-data array returned by `extractQuery`, or `NULL` if none.

When `extractQuery` returns a null key in `queryKeys[]`, the corresponding `check[]` element is true if the indexed item contains a null key; that is, the semantics of `check[]` are like `IS NOT DISTINCT FROM`. The `consistent` function can examine the corresponding `nullFlags[]` element if it needs to tell the difference between a regular value match and a null match.

On success, `*recheck` should be set to true if the heap tuple needs to be rechecked against the query operator, or false if the index test is exact. That is, a false return value guarantees that the heap tuple does not match the query; a true return value with `*recheck` set to false guarantees that the heap tuple does match the query; and a true return value with `*recheck` set to true means that the heap tuple might match the query, so it needs to be fetched and rechecked by evaluating the query operator directly against the originally indexed item.

```
GinTernaryValue triConsistent(GinTernaryValue check[], StrategyNumber n, Datum query, int32 nkeys, Pointer extra_data[], Datum queryKeys[], bool nullFlags[])
```

`triConsistent` is similar to `consistent`, but instead of Booleans in the `check` vector, there are three possible values for each key: `GIN_TRUE`, `GIN_FALSE` and `GIN_MAYBE`. `GIN_FALSE` and `GIN_TRUE` have the same meaning as regular Boolean values, while `GIN_MAYBE` means that the presence of that key is not known. When `GIN_MAYBE` values are present, the function should only return `GIN_TRUE` if the item certainly matches whether or not the index item contains the corresponding query keys. Likewise, the function must return `GIN_FALSE` only if the item certainly does not match, whether or not it contains the `GIN_MAYBE` keys. If the result depends on the `GIN_MAYBE` entries, i.e., the match cannot be confirmed or refuted based on the known query keys, the function must return `GIN_MAYBE`.

When there are no `GIN_MAYBE` values in the `check` vector, a `GIN_MAYBE` return value is the equivalent of setting the `recheck` flag in the Boolean `consistent` function.

In addition, GIN must have a way to sort the key values stored in the index. The operator class can define the sort ordering by specifying a comparison method:

```
int compare(Datum a, Datum b)
```

Compares two keys (not indexed items!) and returns an integer less than zero, zero, or greater than zero, indicating whether the first key is less than, equal to, or greater than the second. Null keys are never passed to this function.

Alternatively, if the operator class does not provide a `compare` method, GIN will look up the default btree operator class for the index key data type, and use its comparison function. It is recommended to specify the comparison function in a GIN operator class that is meant for just one data type, as looking up the btree operator class costs a few cycles. However, polymorphic GIN operator classes (such as `array_ops`) typically cannot specify a single comparison function.

An operator class for GIN can optionally supply the following methods:

```
int comparePartial(Datum partial_key, Datum key, StrategyNumber n, Pointer extra_data)
```

Compare a partial-match query key to an index key. Returns an integer whose sign indicates the result: less than zero means the index key does not match the query, but the index scan should continue; zero means that the index key does match the query; greater than zero indicates that the index scan should stop because no more matches are possible. The strategy number `n` of the operator that generated the partial match query is provided, in case its semantics are needed to determine when to end the scan. Also, `extra_data` is the corresponding element of the extra-data array made by `extractQuery`, or `NULL` if none. Null keys are never passed to this function.

```
void options(local_relopts *relopts)
```

Defines a set of user-visible parameters that control operator class behavior.

The `options` function is passed a pointer to a `local_relopts` struct, which needs to be filled with a set of operator class specific options. The options can be accessed from other support functions using the `PG_HAS_OPCLASS_OPTIONS()` and `PG_GET_OPCLASS_OPTIONS()` macros.

Since both key extraction of indexed values and representation of the key in GIN are flexible, they may depend on user-specified parameters.

To support “partial match” queries, an operator class must provide the `comparePartial` method, and its `extractQuery` method must set the `pmatch` parameter when a partial-match query is encountered. See [Section 67.4.2](#) for details.

The actual data types of the various `Datum` values mentioned above vary depending on the operator class. The item values passed to `extractValue` are always of the operator class's input type, and all key values must be of the class's `STORAGE` type. The type of the `query` argument passed to `extractQuery`, `consistent` and `triConsistent` is whatever is the right-hand input type of the class member operator identified by the strategy number. This need not be the same as the indexed type, so long as key values of the correct type can be extracted from it. However, it is recommended that the SQL declarations of these three support functions use the opclass's indexed data type for the `query` argument, even though the actual type might be something else depending on the operator.

## 67.4. Implementation

Internally, a GIN index contains a B-tree index constructed over keys, where each key is an element of one or more indexed items (a member of an array, for example) and where each tuple in a leaf page contains either a pointer to a B-tree of heap pointers (a “posting tree”), or a simple list of heap pointers (a “posting list”) when the list is small enough to fit into a single index tuple along with the key value. [Figure 67.1](#) illustrates these components of a GIN index.

As of PostgreSQL 9.1, null key values can be included in the index. Also, placeholder nulls are included in the index for indexed items that are null or contain no keys according to `extractValue`. This allows searches that should find empty items to do so.

Multicolumn GIN indexes are implemented by building a single B-tree over composite values (column number, key value). The key values for different columns can be of different types.

**Figure 67.1. GIN Internals**

### 67.4.1. GIN Fast Update Technique

Updating a GIN index tends to be slow because of the intrinsic nature of inverted indexes: inserting or updating one heap row can cause many inserts into the index (one for each key extracted from the indexed item). GIN is capable of postponing much of this work by inserting new tuples into a temporary, unsorted list of pending entries. When the table is vacuumed or autoanalyzed, or when `gin_clean_pending_list` function is called, or if the pending list becomes larger than `gin_pending_list_limit`, the entries are moved to the main GIN data structure using the same bulk insert techniques used during initial index creation. This greatly improves GIN index update speed, even counting the additional vacuum overhead. Moreover the overhead work can be done by a background process instead of in foreground query processing.

The main disadvantage of this approach is that searches must scan the list of pending entries in addition to searching the regular index, and so a large list of pending entries will slow searches significantly. Another disadvantage is that, while most updates are fast, an update that causes the pending list to become “too large” will incur an immediate cleanup cycle and thus be much slower than other updates. Proper use of autovacuum can minimize both of these problems.

If consistent response time is more important than update speed, use of pending entries can be disabled by turning off the `fastupdate` storage parameter for a GIN index. See [CREATE INDEX](#) for details.

### 67.4.2. Partial Match Algorithm

GIN can support “partial match” queries, in which the query does not determine an exact match for one or more keys, but the possible matches fall within a reasonably narrow range of key values (within the key sorting order determined by the `compare` support method). The `extractQuery` method, instead of returning a key value to be matched exactly, returns a key value that is the lower bound of the range to be searched, and sets the `pmatch` flag true. The key range is then scanned using the `comparePartial` method. `comparePartial` must return zero for a matching index key, less than zero for a non-match that is still within the range to be searched, or greater than zero if the index key is past the range that could match.

## 67.5. GIN Tips and Tricks

### Create vs. insert

Insertion into a GIN index can be slow due to the likelihood of many keys being inserted for each item. So, for bulk insertions into a table it is advisable to drop the GIN index and recreate it after finishing bulk insertion.

When `fastupdate` is enabled for GIN (see [Section 67.4.1](#) for details), the penalty is less than when it is not. But for very large updates it may still be best to drop and recreate the index.

### `maintenance_work_mem`

Build time for a GIN index is very sensitive to the `maintenance_work_mem` setting; it doesn't pay to skimp on work memory during index creation.

### `gin_pending_list_limit`

During a series of insertions into an existing GIN index that has `fastupdate` enabled, the system will clean up the pending-entry list whenever the list grows larger than `gin_pending_list_limit`. To avoid fluctuations in observed response time, it's desirable to have pending-list cleanup occur in the background (i.e., via autovacuum). Foreground cleanup operations can be avoided by increasing `gin_pending_list_limit` or making autovacuum more aggressive. However, enlarging the threshold of the cleanup operation means that if a foreground cleanup does occur, it will take even longer.

`gin_pending_list_limit` can be overridden for individual GIN indexes by changing storage parameters, which allows each GIN index to have its own cleanup threshold. For example, it's possible to increase the threshold only for the GIN index which can be updated heavily, and decrease it otherwise.

### `gin_fuzzy_search_limit`

The primary goal of developing GIN indexes was to create support for highly scalable full-text search in Postgres Pro, and there are often situations when a full-text search returns a very large set of results. Moreover, this often happens when the query contains very frequent words, so that the large result set is not even useful. Since reading many tuples from the disk and sorting them could take a lot of time, this is unacceptable for production. (Note that the index search itself is very fast.)

To facilitate controlled execution of such queries, GIN has a configurable soft upper limit on the number of rows returned: the `gin_fuzzy_search_limit` configuration parameter. It is set to 0 (meaning no limit) by default. If a non-zero limit is set, then the returned set is a subset of the whole result set, chosen at random.

“Soft” means that the actual number of returned results could differ somewhat from the specified limit, depending on the query and the quality of the system's random number generator.

From experience, values in the thousands (e.g., 5000 — 20000) work well.

## 67.6. Limitations

GIN assumes that indexable operators are strict. This means that `extractValue` will not be called at all on a null item value (instead, a placeholder index entry is created automatically), and `extractQuery` will not be called on a null query value either (instead, the query is presumed to be unsatisfiable). Note however that null key values contained within a non-null composite item or query value are supported.

## 67.7. Examples

The core Postgres Pro distribution includes the GIN operator classes previously shown in [Table 67.1](#). The following `contrib` modules also contain GIN operator classes:

`btree_gin`

B-tree equivalent functionality for several data types

hstore

Module for storing (key, value) pairs

intarray

Enhanced support for `int[]`

pg\_trgm

Text similarity using trigram matching

---

# Chapter 68. BRIN Indexes

## 68.1. Introduction

BRIN stands for Block Range Index. BRIN is designed for handling very large tables in which certain columns have some natural correlation with their physical location within the table.

BRIN works in terms of *block ranges* (or “page ranges”). A block range is a group of pages that are physically adjacent in the table; for each block range, some summary info is stored by the index. For example, a table storing a store's sale orders might have a date column on which each order was placed, and most of the time the entries for earlier orders will appear earlier in the table as well; a table storing a ZIP code column might have all codes for a city grouped together naturally.

BRIN indexes can satisfy queries via regular bitmap index scans, and will return all tuples in all pages within each range if the summary info stored by the index is *consistent* with the query conditions. The query executor is in charge of rechecking these tuples and discarding those that do not match the query conditions — in other words, these indexes are lossy. Because a BRIN index is very small, scanning the index adds little overhead compared to a sequential scan, but may avoid scanning large parts of the table that are known not to contain matching tuples.

The specific data that a BRIN index will store, as well as the specific queries that the index will be able to satisfy, depend on the operator class selected for each column of the index. Data types having a linear sort order can have operator classes that store the minimum and maximum value within each block range, for instance; geometrical types might store the bounding box for all the objects in the block range.

The size of the block range is determined at index creation time by the `pages_per_range` storage parameter. The number of index entries will be equal to the size of the relation in pages divided by the selected value for `pages_per_range`. Therefore, the smaller the number, the larger the index becomes (because of the need to store more index entries), but at the same time the summary data stored can be more precise and more data blocks can be skipped during an index scan.

### 68.1.1. Index Maintenance

At the time of creation, all existing heap pages are scanned and a summary index tuple is created for each range, including the possibly-incomplete range at the end. As new pages are filled with data, page ranges that are already summarized will cause the summary information to be updated with data from the new tuples. When a new page is created that does not fall within the last summarized range, the range that the new page belongs to does not automatically acquire a summary tuple; those tuples remain unsummarized until a summarization run is invoked later, creating the initial summary for that range.

There are several ways to trigger the initial summarization of a page range. If the table is vacuumed, either manually or by [autovacuum](#), all existing unsummarized page ranges are summarized. Also, if the index's [autosummarize](#) parameter is enabled, which it isn't by default, whenever autovacuum runs in that database, summarization will occur for all unsummarized page ranges that have been filled, regardless of whether the table itself is processed by autovacuum; see below.

Lastly, the following functions can be used:

|                                                     |                                                      |
|-----------------------------------------------------|------------------------------------------------------|
| <code>brin_summarize_new_values(regclass)</code>    | which summarizes all unsummarized ranges;            |
| <code>brin_summarize_range(regclass, bigint)</code> | which summarizes only the range containing the given |
| page, if it is unsummarized.                        |                                                      |

When autosummarization is enabled, a request is sent to `autovacuum` to execute a targeted summarization for a block range when an insertion is detected for the first item of the first page of the next block range, to be fulfilled the next time an autovacuum worker finishes running in the same database. If the request queue is full, the request is not recorded and a message is sent to the server log:

```
LOG:  request for BRIN range summarization for index "brin_wi_idx" page 128 was not
recorded
```

When this happens, the range will remain unsummarized until the next regular vacuum run on the table, or one of the functions mentioned above are invoked.

Conversely, a range can be de-summarized using the `brin_desummarize_range(regclass, bigint)` function, which is useful when the index tuple is no longer a very good representation because the existing values have changed. See [Section 9.27.8](#) for details.

## 68.2. Built-in Operator Classes

The core Postgres Pro distribution includes the BRIN operator classes shown in [Table 68.1](#).

The *minmax* operator classes store the minimum and the maximum values appearing in the indexed column within the range. The *inclusion* operator classes store a value which includes the values in the indexed column within the range. The *bloom* operator classes build a Bloom filter for all values in the range. The *minmax-multi* operator classes store multiple minimum and maximum values, representing values appearing in the indexed column within the range.

**Table 68.1. Built-in BRIN Operator Classes**

| Name              | Indexable Operators      |
|-------------------|--------------------------|
| bit_minmax_ops    | = (bit,bit)              |
|                   | < (bit,bit)              |
|                   | > (bit,bit)              |
|                   | <= (bit,bit)             |
|                   | >= (bit,bit)             |
| box_inclusion_ops | @> (box,point)           |
|                   | << (box,box)             |
|                   | &< (box,box)             |
|                   | &> (box,box)             |
|                   | >> (box,box)             |
|                   | <@ (box,box)             |
|                   | @> (box,box)             |
|                   | ~= (box,box)             |
|                   | && (box,box)             |
|                   | <<  (box,box)            |
|                   | &<  (box,box)            |
|                   | &> (box,box)             |
|                   | >> (box,box)             |
| bpchar_bloom_ops  | = (character,character)  |
| bpchar_minmax_ops | = (character,character)  |
|                   | < (character,character)  |
|                   | <= (character,character) |
|                   | > (character,character)  |
|                   | >= (character,character) |

### 68.2.1. Operator Class Parameters

Some of the built-in operator classes allow specifying parameters affecting behavior of the operator class. Each operator class has its own set of allowed parameters. Only the `bloom` and `minmax-multi` operator classes allow specifying parameters:

`bloom` operator classes accept these parameters:

`n_distinct_per_range`

Defines the estimated number of distinct non-null values in the block range, used by BRIN bloom indexes for sizing of the Bloom filter. It behaves similarly to `n_distinct` option for [ALTER TABLE](#). When set to a positive value, each block range is assumed to contain this number of distinct non-null values. When set to a negative value, which must be greater than or equal to -1, the number of distinct non-null values is assumed to grow linearly with the maximum possible number of tuples in the block range (about 290 rows per block). The default value is `-0.1`, and the minimum number of distinct non-null values is 16.

`false_positive_rate`

Defines the desired false positive rate used by BRIN bloom indexes for sizing of the Bloom filter. The values must be between 0.0001 and 0.25. The default value is 0.01, which is 1% false positive rate.

`minmax-multi` operator classes accept these parameters:

`values_per_range`

Defines the maximum number of values stored by BRIN minmax indexes to summarize a block range. Each value may represent either a point, or a boundary of an interval. Values must be between 8 and 256, and the default value is 32.

## 68.3. Extensibility

The BRIN interface has a high level of abstraction, requiring the access method implementer only to implement the semantics of the data type being accessed. The BRIN layer itself takes care of concurrency, logging and searching the index structure.

All it takes to get a BRIN access method working is to implement a few user-defined methods, which define the behavior of summary values stored in the index and the way they interact with scan keys. In short, BRIN combines extensibility with generality, code reuse, and a clean interface.

There are four methods that an operator class for BRIN must provide:

```
BrinOpcInfo *opcInfo(Oid type_oid)
```

Returns internal information about the indexed columns' summary data. The return value must point to a palloc'd `BrinOpcInfo`, which has this definition:

```
typedef struct BrinOpcInfo
{
    /* Number of columns stored in an index column of this opclass */
    uint16      oi_nstored;

    /* Opaque pointer for the opclass' private use */
    void        *oi_opaque;

    /* Type cache entries of the stored columns */
    TypeCacheEntry *oi_tpcache[FLEXIBLE_ARRAY_MEMBER];
} BrinOpcInfo;
```

`BrinOpcInfo.oi_opaque` can be used by the operator class routines to pass information between support functions during an index scan.

```
bool consistent(BrinDesc *bdesc, BrinValues *column, ScanKey *keys, int nkeys)
```

Returns whether all the `ScanKey` entries are consistent with the given indexed values for a range. The attribute number to use is passed as part of the scan key. Multiple scan keys for the same attribute may be passed at once; the number of entries is determined by the `nkeys` parameter.

```
bool consistent(BrinDesc *bdesc, BrinValues *column, ScanKey key)
```

Returns whether the `ScanKey` is consistent with the given indexed values for a range. The attribute number to use is passed as part of the scan key. This is an older backward-compatible variant of the `consistent` function.

```
bool addValue(BrinDesc *bdesc, BrinValues *column, Datum newval, bool isnull)
```

Given an index tuple and an indexed value, modifies the indicated attribute of the tuple so that it additionally represents the new value. If any modification was done to the tuple, `true` is returned.

```
bool unionTuples(BrinDesc *bdesc, BrinValues *a, BrinValues *b)
```

Consolidates two index tuples. Given two index tuples, modifies the indicated attribute of the first of them so that it represents both tuples. The second tuple is not modified.

An operator class for BRIN can optionally specify the following method:

```
void options(local_relopts *relopts)
```

Defines a set of user-visible parameters that control operator class behavior.

The `options` function is passed a pointer to a `local_relopts` struct, which needs to be filled with a set of operator class specific options. The options can be accessed from other support functions using the `PG_HAS_OPCLASS_OPTIONS()` and `PG_GET_OPCLASS_OPTIONS()` macros.

Since both key extraction of indexed values and representation of the key in BRIN are flexible, they may depend on user-specified parameters.

The core distribution includes support for four types of operator classes: `minmax`, `minmax-multi`, `inclusion` and `bloom`. Operator class definitions using them are shipped for in-core data types as appropriate. Additional operator classes can be defined by the user for other data types using equivalent definitions, without having to write any source code; appropriate catalog entries being declared is enough. Note that assumptions about the semantics of operator strategies are embedded in the support functions' source code.

Operator classes that implement completely different semantics are also possible, provided implementations of the four main support functions described above are written. Note that backwards compatibility across major releases is not guaranteed: for example, additional support functions might be required in later releases.

To write an operator class for a data type that implements a totally ordered set, it is possible to use the minmax support functions alongside the corresponding operators, as shown in [Table 68.2](#). All operator class members (functions and operators) are mandatory.

**Table 68.2. Function and Support Numbers for Minmax Operator Classes**

| Operator class member | Object                                                  |
|-----------------------|---------------------------------------------------------|
| Support Function 1    | internal function <code>brin_minmax_opcinfo()</code>    |
| Support Function 2    | internal function <code>brin_minmax_add_value()</code>  |
| Support Function 3    | internal function <code>brin_minmax_consistent()</code> |
| Support Function 4    | internal function <code>brin_minmax_union()</code>      |
| Operator Strategy 1   | operator less-than                                      |
| Operator Strategy 2   | operator less-than-or-equal-to                          |
| Operator Strategy 3   | operator equal-to                                       |
| Operator Strategy 4   | operator greater-than-or-equal-to                       |
| Operator Strategy 5   | operator greater-than                                   |

To write an operator class for a complex data type which has values included within another type, it's possible to use the inclusion support functions alongside the corresponding operators, as shown in [Table 68.3](#). It requires only a single additional function, which can be written in any language. More functions can be defined for additional functionality. All operators are optional. Some operators require other operators, as shown as dependencies on the table.

**Table 68.3. Function and Support Numbers for Inclusion Operator Classes**

| Operator class member | Object                                                               | Dependency          |
|-----------------------|----------------------------------------------------------------------|---------------------|
| Support Function 1    | internal function <code>brin_inclusion_opcinfo()</code>              |                     |
| Support Function 2    | internal function <code>brin_inclusion_add_value()</code>            |                     |
| Support Function 3    | internal function <code>brin_inclusion_consistent()</code>           |                     |
| Support Function 4    | internal function <code>brin_inclusion_union()</code>                |                     |
| Support Function 11   | function to merge two elements                                       |                     |
| Support Function 12   | optional function to check whether two elements are mergeable        |                     |
| Support Function 13   | optional function to check if an element is contained within another |                     |
| Support Function 14   | optional function to check whether an element is empty               |                     |
| Operator Strategy 1   | operator left-of                                                     | Operator Strategy 4 |
| Operator Strategy 2   | operator does-not-extend-to-the-right-of                             | Operator Strategy 5 |
| Operator Strategy 3   | operator overlaps                                                    |                     |
| Operator Strategy 4   | operator does-not-extend-to-the-left-of                              | Operator Strategy 1 |
| Operator Strategy 5   | operator right-of                                                    | Operator Strategy 2 |

| Operator class member           | Object                               | Dependency           |
|---------------------------------|--------------------------------------|----------------------|
| Operator Strategy 6, 18         | operator same-as-or-equal-to         | Operator Strategy 7  |
| Operator Strategy 7, 16, 24, 25 | operator contains-or-equal-to        |                      |
| Operator Strategy 8, 26, 27     | operator is-contained-by-or-equal-to | Operator Strategy 3  |
| Operator Strategy 9             | operator does-not-extend-above       | Operator Strategy 11 |
| Operator Strategy 10            | operator is-below                    | Operator Strategy 12 |
| Operator Strategy 11            | operator is-above                    | Operator Strategy 9  |
| Operator Strategy 12            | operator does-not-extend-below       | Operator Strategy 10 |
| Operator Strategy 20            | operator less-than                   | Operator Strategy 5  |
| Operator Strategy 21            | operator less-than-or-equal-to       | Operator Strategy 5  |
| Operator Strategy 22            | operator greater-than                | Operator Strategy 1  |
| Operator Strategy 23            | operator greater-than-or-equal-to    | Operator Strategy 1  |

Support function numbers 1 through 10 are reserved for the BRIN internal functions, so the SQL level functions start with number 11. Support function number 11 is the main function required to build the index. It should accept two arguments with the same data type as the operator class, and return the union of them. The inclusion operator class can store union values with different data types if it is defined with the `STORAGE` parameter. The return value of the union function should match the `STORAGE` data type.

Support function numbers 12 and 14 are provided to support irregularities of built-in data types. Function number 12 is used to support network addresses from different families which are not mergeable. Function number 14 is used to support empty ranges. Function number 13 is an optional but recommended one, which allows the new value to be checked before it is passed to the union function. As the BRIN framework can shortcut some operations when the union is not changed, using this function can improve index performance.

To write an operator class for a data type that implements only an equality operator and supports hashing, it is possible to use the bloom support procedures alongside the corresponding operators, as shown in [Table 68.4](#). All operator class members (procedures and operators) are mandatory.

**Table 68.4. Procedure and Support Numbers for Bloom Operator Classes**

| Operator class member | Object                                                 |
|-----------------------|--------------------------------------------------------|
| Support Procedure 1   | internal function <code>brin_bloom_opcinfo()</code>    |
| Support Procedure 2   | internal function <code>brin_bloom_add_value()</code>  |
| Support Procedure 3   | internal function <code>brin_bloom_consistent()</code> |
| Support Procedure 4   | internal function <code>brin_bloom_union()</code>      |
| Support Procedure 5   | internal function <code>brin_bloom_options()</code>    |
| Support Procedure 11  | function to compute hash of an element                 |
| Operator Strategy 1   | operator equal-to                                      |

Support procedure numbers 1-10 are reserved for the BRIN internal functions, so the SQL level functions start with number 11. Support function number 11 is the main function required to build the index. It should accept one argument with the same data type as the operator class, and return a hash of the value.

The minmax-multi operator class is also intended for data types implementing a totally ordered set, and may be seen as a simple extension of the minmax operator class. While minmax operator class summarizes values from each block range into a single contiguous interval, minmax-multi allows summarization into multiple smaller intervals to improve handling of outlier values. It is possible to use the

minmax-multi support procedures alongside the corresponding operators, as shown in [Table 68.5](#). All operator class members (procedures and operators) are mandatory.

**Table 68.5. Procedure and Support Numbers for minmax-multi Operator Classes**

| Operator class member | Object                                                              |
|-----------------------|---------------------------------------------------------------------|
| Support Procedure 1   | internal function <code>brin_minmax_multi_opcin-fo()</code>         |
| Support Procedure 2   | internal function <code>brin_minmax_multi_add_value()</code>        |
| Support Procedure 3   | internal function <code>brin_minmax_multi_consistent()</code>       |
| Support Procedure 4   | internal function <code>brin_minmax_multi_union()</code>            |
| Support Procedure 5   | internal function <code>brin_minmax_multi_options()</code>          |
| Support Procedure 11  | function to compute distance between two values (length of a range) |
| Operator Strategy 1   | operator less-than                                                  |
| Operator Strategy 2   | operator less-than-or-equal-to                                      |
| Operator Strategy 3   | operator equal-to                                                   |
| Operator Strategy 4   | operator greater-than-or-equal-to                                   |
| Operator Strategy 5   | operator greater-than                                               |

Both minmax and inclusion operator classes support cross-data-type operators, though with these the dependencies become more complicated. The minmax operator class requires a full set of operators to be defined with both arguments having the same data type. It allows additional data types to be supported by defining extra sets of operators. Inclusion operator class operator strategies are dependent on another operator strategy as shown in [Table 68.3](#), or the same operator strategy as themselves. They require the dependency operator to be defined with the `STORAGE` data type as the left-hand-side argument and the other supported data type to be the right-hand-side argument of the supported operator. See `float4_minmax_ops` as an example of minmax, and `box_inclusion_ops` as an example of inclusion.

---

# Chapter 69. Hash Indexes

## 69.1. Overview

Postgres Pro includes an implementation of persistent on-disk hash indexes, which are fully crash recoverable. Any data type can be indexed by a hash index, including data types that do not have a well-defined linear ordering. Hash indexes store only the hash value of the data being indexed, thus there are no restrictions on the size of the data column being indexed.

Hash indexes support only single-column indexes and do not allow uniqueness checking.

Hash indexes support only the = operator, so WHERE clauses that specify range operations will not be able to take advantage of hash indexes.

Each hash index tuple stores just the 4-byte hash value, not the actual column value. As a result, hash indexes may be much smaller than B-trees when indexing longer data items such as UUIDs, URLs, etc. The absence of the column value also makes all hash index scans lossy. Hash indexes may take part in bitmap index scans and backward scans.

Hash indexes are best optimized for SELECT and UPDATE-heavy workloads that use equality scans on larger tables. In a B-tree index, searches must descend through the tree until the leaf page is found. In tables with millions of rows, this descent can increase access time to data. The equivalent of a leaf page in a hash index is referred to as a bucket page. In contrast, a hash index allows accessing the bucket pages directly, thereby potentially reducing index access time in larger tables. This reduction in "logical I/O" becomes even more pronounced on indexes/data larger than `shared_buffers`/RAM.

Hash indexes have been designed to cope with uneven distributions of hash values. Direct access to the bucket pages works well if the hash values are evenly distributed. When inserts mean that the bucket page becomes full, additional overflow pages are chained to that specific bucket page, locally expanding the storage for index tuples that match that hash value. When scanning a hash bucket during queries, we need to scan through all of the overflow pages. Thus an unbalanced hash index might actually be worse than a B-tree in terms of number of block accesses required, for some data.

As a result of the overflow cases, we can say that hash indexes are most suitable for unique, nearly unique data or data with a low number of rows per hash bucket. One possible way to avoid problems is to exclude highly non-unique values from the index using a partial index condition, but this may not be suitable in many cases.

Like B-Trees, hash indexes perform simple index tuple deletion. This is a deferred maintenance operation that deletes index tuples that are known to be safe to delete (those whose item identifier's LP\_DEAD bit is already set). If an insert finds no space is available on a page we try to avoid creating a new overflow page by attempting to remove dead index tuples. Removal cannot occur if the page is pinned at that time. Deletion of dead index pointers also occurs during VACUUM.

If it can, VACUUM will also try to squeeze the index tuples onto as few overflow pages as possible, minimizing the overflow chain. If an overflow page becomes empty, overflow pages can be recycled for reuse in other buckets, though we never return them to the operating system. There is currently no provision to shrink a hash index, other than by rebuilding it with REINDEX. There is no provision for reducing the number of buckets, either.

Hash indexes may expand the number of bucket pages as the number of rows indexed grows. The hash key-to-bucket-number mapping is chosen so that the index can be incrementally expanded. When a new bucket is to be added to the index, exactly one existing bucket will need to be "split", with some of its tuples being transferred to the new bucket according to the updated key-to-bucket-number mapping.

The expansion occurs in the foreground, which could increase execution time for user inserts. Thus, hash indexes may not be suitable for tables with rapidly increasing number of rows.

## 69.2. Implementation

There are four kinds of pages in a hash index: the meta page (page zero), which contains statically allocated control information; primary bucket pages; overflow pages; and bitmap pages, which keep track of overflow pages that have been freed and are available for re-use. For addressing purposes, bitmap pages are regarded as a subset of the overflow pages.

Both scanning the index and inserting tuples require locating the bucket where a given tuple ought to be located. To do this, we need the bucket count, highmask, and lowmask from the metapage; however, it's undesirable for performance reasons to have to have to lock and pin the metapage for every such operation. Instead, we retain a cached copy of the metapage in each backend's relcache entry. This will produce the correct bucket mapping as long as the target bucket hasn't been split since the last cache refresh.

Primary bucket pages and overflow pages are allocated independently since any given index might need more or fewer overflow pages relative to its number of buckets. The hash code uses an interesting set of addressing rules to support a variable number of overflow pages while not having to move primary bucket pages around after they are created.

Each row in the table indexed is represented by a single index tuple in the hash index. Hash index tuples are stored in bucket pages, and if they exist, overflow pages. We speed up searches by keeping the index entries in any one index page sorted by hash code, thus allowing binary search to be used within an index page. Note however that there is *\*no\** assumption about the relative ordering of hash codes across different index pages of a bucket.

The bucket splitting algorithms to expand the hash index are too complex to be worthy of mention here. The split algorithm is crash safe and can be restarted if not completed successfully.

---

# Chapter 70. Database Physical Storage

This chapter provides an overview of the physical storage format used by Postgres Pro databases.

## 70.1. Database File Layout

This section describes the storage format at the level of files and directories.

Traditionally, the configuration and data files used by a database cluster are stored together within the cluster's data directory, commonly referred to as `PGDATA` (after the name of the environment variable that can be used to define it). A common location for `PGDATA` is `/var/lib/pgpro/ent-14/data`. Multiple clusters, managed by different server instances, can exist on the same machine.

The `PGDATA` directory contains several subdirectories and control files, as shown in [Table 70.1](#). In addition to these required items, the cluster configuration files `postgresql.conf`, `pg_hba.conf`, and `pg_ident.conf` are traditionally stored in `PGDATA`, although it is possible to place them elsewhere.

**Table 70.1. Contents of `PGDATA`**

| Item                          | Description                                                                      |
|-------------------------------|----------------------------------------------------------------------------------|
| <code>PG_VERSION</code>       | A file containing the major version number of Postgres Pro                       |
| <code>base</code>             | Subdirectory containing per-database subdirectories                              |
| <code>current_logfiles</code> | File recording the log file(s) currently written to by the logging collector     |
| <code>global</code>           | Subdirectory containing cluster-wide tables, such as <code>pg_database</code>    |
| <code>pg_commit_ts</code>     | Subdirectory containing transaction commit timestamp data                        |
| <code>pg_dynshmem</code>      | Subdirectory containing files used by the dynamic shared memory subsystem        |
| <code>pg_logical</code>       | Subdirectory containing status data for logical decoding                         |
| <code>pg_multixact</code>     | Subdirectory containing multitransaction status data (used for shared row locks) |
| <code>pg_notify</code>        | Subdirectory containing LISTEN/NOTIFY status data                                |
| <code>pg_replslot</code>      | Subdirectory containing replication slot data                                    |
| <code>pg_serial</code>        | Subdirectory containing information about committed serializable transactions    |
| <code>pg_snapshots</code>     | Subdirectory containing exported snapshots                                       |
| <code>pg_stat</code>          | Subdirectory containing permanent files for the statistics subsystem             |
| <code>pg_stat_tmp</code>      | Subdirectory containing temporary files for the statistics subsystem             |
| <code>pg_subtrans</code>      | Subdirectory containing subtransaction status data                               |
| <code>pg_tblspc</code>        | Subdirectory containing symbolic links to tablespaces                            |
| <code>pg_twophase</code>      | Subdirectory containing state files for prepared transactions                    |

| Item                              | Description                                                                                                                                                                                                                                                                                                                                            |
|-----------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>pg_wal</code>               | Subdirectory containing WAL (Write Ahead Log) files                                                                                                                                                                                                                                                                                                    |
| <code>pg_xact</code>              | Subdirectory containing transaction commit status data                                                                                                                                                                                                                                                                                                 |
| <code>postgresql.auto.conf</code> | A file used for storing configuration parameters that are set by <code>ALTER SYSTEM</code>                                                                                                                                                                                                                                                             |
| <code>postmaster.opts</code>      | A file recording the command-line options the server was last started with                                                                                                                                                                                                                                                                             |
| <code>postmaster.pid</code>       | A lock file recording the current postmaster process ID (PID), cluster data directory path, postmaster start timestamp, port number, Unix-domain socket directory path (could be empty), first valid listen_address (IP address or *, or empty if not listening on TCP), and shared memory segment ID (this file is not present after server shutdown) |

For each database in the cluster there is a subdirectory within `PGDATA/base`, named after the database's OID in `pg_database`. This subdirectory is the default location for the database's files; in particular, its system catalogs are stored there.

Note that the following sections describe the behavior of the builtin heap [table access method](#), and the builtin [index access methods](#). Due to the extensible nature of Postgres Pro, other access methods might work differently.

Each table and index is stored in a separate file. For ordinary relations, these files are named after the table or index's *filenode* number, which can be found in `pg_class.relfilenode`. But for temporary relations, the file name is of the form `tBBB_FFF`, where *BBB* is the backend ID of the backend which created the file, and *FFF* is the filenode number. In either case, in addition to the main file (a/k/a main fork), each table and index has a *free space map* (see [Section 70.3](#)), which stores information about free space available in the relation. The free space map is stored in a file named with the filenode number plus the suffix `_fsm`. Tables also have a *visibility map*, stored in a fork with the suffix `_vm`, to track which pages are known to have no dead tuples. The visibility map is described further in [Section 70.4](#). Unlogged tables and indexes have a third fork, known as the initialization fork, which is stored in a fork with the suffix `_init` (see [Section 70.5](#)).

### Caution

Note that while a table's filenode often matches its OID, this is *not* necessarily the case; some operations, like `TRUNCATE`, `REINDEX`, `CLUSTER` and some forms of `ALTER TABLE`, can change the filenode while preserving the OID. Avoid assuming that filenode and table OID are the same. Also, for certain system catalogs including `pg_class` itself, `pg_class.relfilenode` contains zero. The actual filenode number of these catalogs is stored in a lower-level data structure, and can be obtained using the `pg_relation_filenode()` function.

When a table or index exceeds 1 GB, it is divided into gigabyte-sized *segments*. The first segment's file name is the same as the filenode; subsequent segments are named `filenode.1`, `filenode.2`, etc. This arrangement avoids problems on platforms that have file size limitations. (Actually, 1 GB is just the default segment size. The segment size can be adjusted using the configuration option `--with-segsize` when building Postgres Pro.) In principle, free space map and visibility map forks could require multiple segments as well, though this is unlikely to happen in practice.

A table that has columns with potentially large entries will have an associated *TOAST* table, which is used for out-of-line storage of field values that are too large to keep in the table rows proper. `pg_class.reltoastrelid` links from a table to its TOAST table, if any. See [Section 70.2](#) for more information.

The contents of tables and indexes are discussed further in [Section 70.6](#).

Tablespaces make the scenario more complicated. Each user-defined tablespace has a symbolic link inside the `PGDATA/pg_tblspc` directory, which points to the physical tablespace directory (i.e., the location specified in the tablespace's `CREATE TABLESPACE` command). This symbolic link is named after the tablespace's OID. Inside the physical tablespace directory there is a subdirectory with a name that depends on the Postgres Pro server version, such as `PG_9.0_201008051`. (The reason for using this subdirectory is so that successive versions of the database can use the same `CREATE TABLESPACE` location value without conflicts.) Within the version-specific subdirectory, there is a subdirectory for each database that has elements in the tablespace, named after the database's OID. Tables and indexes are stored within that directory, using the filenode naming scheme. The `pg_default` tablespace is not accessed through `pg_tblspc`, but corresponds to `PGDATA/base`. Similarly, the `pg_global` tablespace is not accessed through `pg_tblspc`, but corresponds to `PGDATA/global`.

The `pg_relation_filepath()` function shows the entire path (relative to `PGDATA`) of any relation. It is often useful as a substitute for remembering many of the above rules. But keep in mind that this function just gives the name of the first segment of the main fork of the relation — you may need to append a segment number and/or `_fsm`, `_vm`, or `_init` to find all the files associated with the relation.

Temporary files (for operations such as sorting more data than can fit in memory) are created within `PGDATA/base/pgsql_tmp`, or within a `pgsql_tmp` subdirectory of a tablespace directory if a tablespace other than `pg_default` is specified for them. The name of a temporary file has the form `pgsql_tmpPPP-P.NNN`, where `PPP` is the PID of the owning backend and `NNN` distinguishes different temporary files of that backend.

## 70.2. TOAST

This section provides an overview of TOAST (The Oversized-Attribute Storage Technique).

Postgres Pro uses a fixed page size (commonly 8 kB), and does not allow tuples to span multiple pages. Therefore, it is not possible to store very large field values directly. To overcome this limitation, large field values are compressed and/or broken up into multiple physical rows. This happens transparently to the user, with only small impact on most of the backend code. The technique is affectionately known as TOAST (or “the best thing since sliced bread”). The TOAST infrastructure is also used to improve handling of large data values in-memory.

Only certain data types support TOAST — there is no need to impose the overhead on data types that cannot produce large field values. To support TOAST, a data type must have a variable-length (*varlena*) representation, in which, ordinarily, the first four-byte word of any stored value contains the total length of the value in bytes (including itself). TOAST does not constrain the rest of the data type's representation. The special representations collectively called *TOASTed values* work by modifying or reinterpreting this initial length word. Therefore, the C-level functions supporting a TOAST-able data type must be careful about how they handle potentially TOASTed input values: an input might not actually consist of a four-byte length word and contents until after it's been *detoasted*. (This is normally done by invoking `PG_DETOAST_DATUM` before doing anything with an input value, but in some cases more efficient approaches are possible. See [Section 40.13.1](#) for more detail.)

TOAST usurps two bits of the *varlena* length word (the high-order bits on big-endian machines, the low-order bits on little-endian machines), thereby limiting the logical size of any value of a TOAST-able data type to 1 GB ( $2^{30}$  - 1 bytes). When both bits are zero, the value is an ordinary un-TOASTed value of the data type, and the remaining bits of the length word give the total datum size (including length word) in bytes. When the highest-order or lowest-order bit is set, the value has only a single-byte header instead of the normal four-byte header, and the remaining bits of that byte give the total datum size (including length byte) in bytes. This alternative supports space-efficient storage of values shorter than 127 bytes, while still allowing the data type to grow to 1 GB at need. Values with single-byte headers aren't aligned on any particular boundary, whereas values with four-byte headers are aligned on at least a four-byte boundary; this omission of alignment padding provides additional space savings that is significant compared to short values. As a special case, if the remaining bits of a single-byte header are all zero (which would be impossible for a self-inclusive length), the value is a pointer to out-of-line

data, with several possible alternatives as described below. The type and size of such a *TOAST pointer* are determined by a code stored in the second byte of the datum. Lastly, when the highest-order or lowest-order bit is clear but the adjacent bit is set, the content of the datum has been compressed and must be decompressed before use. In this case the remaining bits of the four-byte length word give the total size of the compressed datum, not the original data. Note that compression is also possible for out-of-line data but the varlena header does not tell whether it has occurred — the content of the TOAST pointer tells that, instead.

The compression technique used for either in-line or out-of-line compressed data can be selected for each column by setting the `COMPRESSION` column option in `CREATE TABLE` or `ALTER TABLE`. The default for columns with no explicit setting is to consult the `default_toast_compression` parameter at the time data is inserted.

As mentioned, there are multiple types of TOAST pointer datums. The oldest and most common type is a pointer to out-of-line data stored in a *TOAST table* that is separate from, but associated with, the table containing the TOAST pointer datum itself. These *on-disk* pointer datums are created by the TOAST management code when a tuple to be stored on disk is too large to be stored as-is. Further details appear in [Section 70.2.1](#). Alternatively, a TOAST pointer datum can contain a pointer to out-of-line data that appears elsewhere in memory. Such datums are necessarily short-lived, and will never appear on-disk, but they are very useful for avoiding copying and redundant processing of large data values. Further details appear in [Section 70.2.2](#).

### 70.2.1. Out-of-Line, On-Disk TOAST Storage

If any of the columns of a table are TOAST-able, the table will have an associated TOAST table, whose OID is stored in the table's `pg_class.reltoastrelid` entry. On-disk TOASTed values are kept in the TOAST table, as described in more detail below.

Out-of-line values are divided (after compression if used) into chunks of at most `TOAST_MAX_CHUNK_SIZE` bytes (by default this value is chosen so that four chunk rows will fit on a page, making it about 2000 bytes). Each chunk is stored as a separate row in the TOAST table belonging to the owning table. Every TOAST table has the columns `chunk_id` (an OID identifying the particular TOASTed value), `chunk_seq` (a sequence number for the chunk within its value), and `chunk_data` (the actual data of the chunk). A unique index on `chunk_id` and `chunk_seq` provides fast retrieval of the values. A pointer datum representing an out-of-line on-disk TOASTed value therefore needs to store the OID of the TOAST table in which to look and the OID of the specific value (its `chunk_id`). For convenience, pointer datums also store the logical datum size (original uncompressed data length), physical stored size (different if compression was applied), and the compression method used, if any. Allowing for the varlena header bytes, the total size of an on-disk TOAST pointer datum is therefore 18 bytes regardless of the actual size of the represented value.

The TOAST management code is triggered only when a row value to be stored in a table is wider than `TOAST_TUPLE_THRESHOLD` bytes (normally 2 kB). The TOAST code will compress and/or move field values out-of-line until the row value is shorter than `TOAST_TUPLE_TARGET` bytes (also normally 2 kB, adjustable) or no more gains can be had. During an `UPDATE` operation, values of unchanged fields are normally preserved as-is; so an `UPDATE` of a row with out-of-line values incurs no TOAST costs if none of the out-of-line values change.

The TOAST management code recognizes four different strategies for storing TOAST-able columns on disk:

- `PLAIN` prevents either compression or out-of-line storage. This is the only possible strategy for columns of non-TOAST-able data types.
- `EXTENDED` allows both compression and out-of-line storage. This is the default for most TOAST-able data types. Compression will be attempted first, then out-of-line storage if the row is still too big.
- `EXTERNAL` allows out-of-line storage but not compression. Use of `EXTERNAL` will make substring operations on wide `text` and `bytea` columns faster (at the penalty of increased storage space) because these operations are optimized to fetch only the required parts of the out-of-line value when it is not compressed.

- `MAIN` allows compression but not out-of-line storage. (Actually, out-of-line storage will still be performed for such columns, but only as a last resort when there is no other way to make the row small enough to fit on a page.)

Each TOAST-able data type specifies a default strategy for columns of that data type, but the strategy for a given table column can be altered with `ALTER TABLE ... SET STORAGE`.

`TOAST_TUPLE_TARGET` can be adjusted for each table using `ALTER TABLE ... SET (toast_tuple_target = N)`

This scheme has a number of advantages compared to a more straightforward approach such as allowing row values to span pages. Assuming that queries are usually qualified by comparisons against relatively small key values, most of the work of the executor will be done using the main row entry. The big values of TOASTed attributes will only be pulled out (if selected at all) at the time the result set is sent to the client. Thus, the main table is much smaller and more of its rows fit in the shared buffer cache than would be the case without any out-of-line storage. Sort sets shrink also, and sorts will more often be done entirely in memory. A little test showed that a table containing typical HTML pages and their URLs was stored in about half of the raw data size including the TOAST table, and that the main table contained only about 10% of the entire data (the URLs and some small HTML pages). There was no run time difference compared to an un-TOASTed comparison table, in which all the HTML pages were cut down to 7 kB to fit.

### 70.2.2. Out-of-Line, In-Memory TOAST Storage

TOAST pointers can point to data that is not on disk, but is elsewhere in the memory of the current server process. Such pointers obviously cannot be long-lived, but they are nonetheless useful. There are currently two sub-cases: pointers to *indirect* data and pointers to *expanded* data.

Indirect TOAST pointers simply point at a non-indirect varlena value stored somewhere in memory. This case was originally created merely as a proof of concept, but it is currently used during logical decoding to avoid possibly having to create physical tuples exceeding 1 GB (as pulling all out-of-line field values into the tuple might do). The case is of limited use since the creator of the pointer datum is entirely responsible that the referenced data survives for as long as the pointer could exist, and there is no infrastructure to help with this.

Expanded TOAST pointers are useful for complex data types whose on-disk representation is not especially suited for computational purposes. As an example, the standard varlena representation of a Postgres Pro array includes dimensionality information, a nulls bitmap if there are any null elements, then the values of all the elements in order. When the element type itself is variable-length, the only way to find the *N*th element is to scan through all the preceding elements. This representation is appropriate for on-disk storage because of its compactness, but for computations with the array it's much nicer to have an "expanded" or "deconstructed" representation in which all the element starting locations have been identified. The TOAST pointer mechanism supports this need by allowing a pass-by-reference Datum to point to either a standard varlena value (the on-disk representation) or a TOAST pointer that points to an expanded representation somewhere in memory. The details of this expanded representation are up to the data type, though it must have a standard header and meet the other API requirements given in `src/include/utils/expandeddatum.h`. C-level functions working with the data type can choose to handle either representation. Functions that do not know about the expanded representation, but simply apply `PG_DETOAST_DATUM` to their inputs, will automatically receive the traditional varlena representation; so support for an expanded representation can be introduced incrementally, one function at a time.

TOAST pointers to expanded values are further broken down into *read-write* and *read-only* pointers. The pointed-to representation is the same either way, but a function that receives a read-write pointer is allowed to modify the referenced value in-place, whereas one that receives a read-only pointer must not; it must first create a copy if it wants to make a modified version of the value. This distinction and some associated conventions make it possible to avoid unnecessary copying of expanded values during query execution.

For all types of in-memory TOAST pointer, the TOAST management code ensures that no such pointer datum can accidentally get stored on disk. In-memory TOAST pointers are automatically expanded to

normal in-line varlena values before storage — and then possibly converted to on-disk TOAST pointers, if the containing tuple would otherwise be too big.

## 70.3. Free Space Map

Each heap and index relation, except for hash indexes, has a Free Space Map (FSM) to keep track of available space in the relation. It's stored alongside the main relation data in a separate relation fork, named after the filenode number of the relation, plus a `_fsm` suffix. For example, if the filenode of a relation is 12345, the FSM is stored in a file called `12345_fsm`, in the same directory as the main relation file.

The Free Space Map is organized as a tree of FSM pages. The bottom level FSM pages store the free space available on each heap (or index) page, using one byte to represent each such page. The upper levels aggregate information from the lower levels.

Within each FSM page is a binary tree, stored in an array with one byte per node. Each leaf node represents a heap page, or a lower level FSM page. In each non-leaf node, the higher of its children's values is stored. The maximum value in the leaf nodes is therefore stored at the root.

The `pg_freespacemap` module can be used to examine the information stored in free space maps.

## 70.4. Visibility Map

Each heap relation has a Visibility Map (VM) to keep track of which pages contain only tuples that are known to be visible to all active transactions; it also keeps track of which pages contain only frozen tuples. It's stored alongside the main relation data in a separate relation fork, named after the filenode number of the relation, plus a `_vm` suffix. For example, if the filenode of a relation is 12345, the VM is stored in a file called `12345_vm`, in the same directory as the main relation file. Note that indexes do not have VMs.

The visibility map stores two bits per heap page. The first bit, if set, indicates that the page is all-visible, or in other words that the page does not contain any tuples that need to be vacuumed. This information can also be used by *index-only scans* to answer queries using only the index tuple. The second bit, if set, means that all tuples on the page have been frozen.

The map is conservative in the sense that we make sure that whenever a bit is set, we know the condition is true, but if a bit is not set, it might or might not be true. Visibility map bits are only set by vacuum, but are cleared by any data-modifying operations on a page.

The `pg_visibility` module can be used to examine the information stored in the visibility map.

## 70.5. The Initialization Fork

Each unlogged table, and each index on an unlogged table, has an initialization fork. The initialization fork is an empty table or index of the appropriate type. When an unlogged table must be reset to empty due to a crash, the initialization fork is copied over the main fork, and any other forks are erased (they will be recreated automatically as needed).

## 70.6. Database Page Layout

This section provides an overview of the page format used within Postgres Pro tables and indexes.<sup>1</sup> Sequences and TOAST tables are formatted just like a regular table.

In the following explanation, a *byte* is assumed to contain 8 bits. In addition, the term *item* refers to an individual data value that is stored on a page. In a table, an item is a row; in an index, an item is an index entry.

---

<sup>1</sup> Actually, use of this page format is not required for either table or index access methods. The `heap` table access method always uses this format. All the existing index methods also use the basic format, but the data kept on index metapages usually doesn't follow the item layout rules.

Every table and index is stored as an array of *pages* of a fixed size (usually 8 kB, although a different page size can be selected when compiling the server). In a table, all the pages are logically equivalent, so a particular item (row) can be stored in any page. In indexes, the first page is generally reserved as a *metapage* holding control information, and there can be different types of pages within the index, depending on the index access method.

[Table 70.2](#) shows the overall layout of a page. There are five parts to each page.

**Table 70.2. Overall Page Layout**

| Item           | Description                                                                                                                                                    |
|----------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------|
| PageHeaderData | 24 bytes long. Contains general information about the page, including free space pointers.                                                                     |
| ItemIdData     | Array of item identifiers pointing to the actual items. Each entry is an (offset,length) pair. 4 bytes per item.                                               |
| Free space     | The unallocated space. New item identifiers are allocated from the start of this area, new items from the end.                                                 |
| Items          | The actual items themselves.                                                                                                                                   |
| Special space  | Index access method specific data. Different methods store different data. Additionally, this space is used to store information about 64-bit transaction IDs. |

The first 20 bytes of each page consists of a page header (`PageHeaderData`). Its format is detailed in [Table 70.3](#). The first field tracks the most recent WAL entry related to this page. The second field contains the page checksum if [data checksums](#) are enabled. Next is a 2-byte field containing flag bits. This is followed by three 2-byte integer fields (`pd_lower`, `pd_upper`, and `pd_special`). These contain byte offsets from the page start to the start of unallocated space, to the end of unallocated space, and to the start of the special space. The next 2 bytes of the page header, `pd_pagesize_version`, store both the page size and a version indicator. Beginning with PostgreSQL 8.3 the version number is 4; PostgreSQL 8.1 and 8.2 used version number 3; PostgreSQL 8.0 used version number 2; PostgreSQL 7.3 and 7.4 used version number 1; prior releases used version number 0. (The basic page layout and header format has not changed in most of these versions, but the layout of heap row headers has.) The page size is basically only present as a cross-check; there is no support for having more than one page size in an installation.

**Table 70.3. PageHeaderData Layout**

| Field                            | Type                        | Length  | Description                                                               |
|----------------------------------|-----------------------------|---------|---------------------------------------------------------------------------|
| <code>pd_lsn</code>              | <code>PageXLogRecPtr</code> | 8 bytes | LSN: next byte after last byte of WAL record for last change to this page |
| <code>pd_checksum</code>         | <code>uint16</code>         | 2 bytes | Page checksum                                                             |
| <code>pd_flags</code>            | <code>uint16</code>         | 2 bytes | Flag bits                                                                 |
| <code>pd_lower</code>            | <code>LocationIndex</code>  | 2 bytes | Offset to start of free space                                             |
| <code>pd_upper</code>            | <code>LocationIndex</code>  | 2 bytes | Offset to end of free space                                               |
| <code>pd_special</code>          | <code>LocationIndex</code>  | 2 bytes | Offset to start of special space                                          |
| <code>pd_pagesize_version</code> | <code>uint16</code>         | 2 bytes | Page size and layout version number information                           |

Following the page header are item identifiers (`ItemIdData`), each requiring four bytes. An item identifier contains a byte-offset to the start of an item, its length in bytes, and a few attribute bits which affect its interpretation. New item identifiers are allocated as needed from the beginning of the unallocated space. The number of item identifiers present can be determined by looking at `pd_lower`, which is increased to allocate a new identifier. Because an item identifier is never moved until it is freed, its index can be used on a long-term basis to reference an item, even when the item itself is moved around on the page to compact free space. In fact, every pointer to an item (`ItemPointer`, also known as `CTID`) created by Postgres Pro consists of a page number and the index of an item identifier.

The items themselves are stored in space allocated backwards from the end of unallocated space. The exact structure varies depending on what the table is to contain. Tables and sequences both use a structure named `HeapTupleHeaderData`, described below.

The final section is the “special section” which can contain anything the access method wishes to store. For example, b-tree indexes store links to the page's left and right siblings, as well as some other data relevant to the index structure. Ordinary tables and sequences store the `HeapPageSpecialData` structure in this section. Its format is specified in [Table 70.4](#).

[Figure 70.1](#) illustrates how these parts are laid out in a page.

**Figure 70.1. Page Layout**

### 70.6.1. Table Row Layout

`HeapPageSpecialData` is a 24-byte structure. The first two 8-byte fields contain the base (i.e., an offset) for short (4-byte) transaction IDs in this page. The next field is a hint that shows whether pruning the page is likely to be profitable: it tracks the oldest un-pruned XMAX on the page. The last field is a magic number identifying the type of the page (0x1010 for ordinary tables and 0x1717 for sequences).

**Table 70.4. `HeapPageSpecialData` Layout**

| Field                      | Type                            | Length  | Description                                        |
|----------------------------|---------------------------------|---------|----------------------------------------------------|
| <code>pd_xid_base</code>   | <code>TransactionId</code>      | 8 bytes | Base for short 4-byte transaction IDs in this page |
| <code>pd_multi_base</code> | <code>TransactionId</code>      | 8 bytes | Base for short 4-byte multixact IDs in this page   |
| <code>pd_prune_xid</code>  | <code>ShortTransactionId</code> | 4 bytes | Oldest unpruned XMAX on page, or zero if none      |
| <code>pd_magic</code>      | <code>uint32</code>             | 4 bytes | Magic number identifying the type of this page     |

All table rows are structured in the same way. There is a fixed-size header (occupying 40 bytes on most machines), followed by an optional null bitmap, an optional object ID field, and the user data. The header is detailed in [Table 70.5](#). The actual user data (columns of the row) begins at the offset indicated by `t_hoff`, which must always be a multiple of the `MAXALIGN` distance for the platform. The null bitmap is only present if the `HEAP_HASNULL` bit is set in `t_infomask`. If it is present it begins just after the fixed header and occupies enough bytes to have one bit per data column (that is, the number of bits that equals the attribute count in `t_infomask2`). In this list of bits, a 1 bit indicates not-null, a 0 bit is a null. When the bitmap is not present, all columns are assumed not-null. The object ID is only present if the `HEAP_HASOID_OLD` bit is set in `t_infomask`. If present, it appears just before the `t_hoff` boundary. Any padding needed to make `t_hoff` a `MAXALIGN` multiple will appear between the null bitmap and the object ID. (This in turn ensures that the object ID is suitably aligned.)

**Table 70.5. HeapTupleHeaderData Layout**

| Field                    | Type               | Length  | Description                                                         |
|--------------------------|--------------------|---------|---------------------------------------------------------------------|
| <code>t_xmin</code>      | ShortTransactionId | 4 bytes | insert XID stamp                                                    |
| <code>t_xmax</code>      | ShortTransactionId | 4 bytes | delete XID stamp                                                    |
| <code>t_cid</code>       | CommandId          | 4 bytes | insert and/or delete CID stamp (overlays with <code>t_xvac</code> ) |
| <code>t_xvac</code>      | ShortTransactionId | 4 bytes | XID for VACUUM operation moving a row version                       |
| <code>t_ctid</code>      | ItemPointerData    | 6 bytes | current TID of this or newer row version                            |
| <code>t_infomask2</code> | uint16             | 2 bytes | number of attributes, plus various flag bits                        |
| <code>t_infomask</code>  | uint16             | 2 bytes | various flag bits                                                   |
| <code>t_hoff</code>      | uint8              | 1 byte  | offset to user data                                                 |

Interpreting the actual data can only be done with information obtained from other tables, mostly `pg_attribute`. The key values needed to identify field locations are `attlen` and `attalign`. There is no way to directly get a particular attribute, except when there are only fixed width fields and no null values. All this trickery is wrapped up in the functions `heap_getattr`, `fastgetattr` and `heap_getsysattr`.

To read the data you need to examine each attribute in turn. First check whether the field is NULL according to the null bitmap. If it is, go to the next. Then make sure you have the right alignment. If the field is a fixed width field, then all the bytes are simply placed. If it's a variable length field (`attlen = -1`) then it's a bit more complicated. All variable-length data types share the common header structure `struct varlena`, which includes the total length of the stored value and some flag bits. Depending on the flags, the data can be either inline or in a TOAST table; it might be compressed, too (see [Section 70.2](#)).

## 70.7. Heap-Only Tuples (HOT)

To allow for high concurrency, PostgreSQL uses [multiversion concurrency control](#) (MVCC) to store rows. However, MVCC has some downsides for update queries. Specifically, updates require new versions of rows to be added to tables. This can also require new index entries for each updated row, and removal of old versions of rows and their index entries can be expensive.

To help reduce the overhead of updates, PostgreSQL has an optimization called heap-only tuples (HOT). This optimization is possible when:

- The update does not modify any columns referenced by the table's indexes, including expression and partial indexes.
- There is sufficient free space on the page containing the old row for the updated row.

In such cases, heap-only tuples provide two optimizations:

- New index entries are not needed to represent updated rows.
- Old versions of updated rows can be completely removed during normal operation, including `SELECTs`, instead of requiring periodic vacuum operations. (This is possible because indexes do not reference their [page item identifiers](#).)

In summary, heap-only tuple updates can only be created if columns used by indexes are not updated. You can increase the likelihood of sufficient page space for HOT updates by decreasing a table's `fillfactor`. If you don't, HOT updates will still happen because new rows will naturally migrate to new pages and existing pages with sufficient free space for new row versions. The system view `pg_stat_all_tables` allows monitoring of the occurrence of HOT and non-HOT updates.

---

# Chapter 71. How the Planner Uses Statistics

This chapter builds on the material covered in [Section 14.1](#) and [Section 14.2](#) to show some additional details about how the planner uses the system statistics to estimate the number of rows each part of a query might return. This is a significant part of the planning process, providing much of the raw material for cost calculation.

The intent of this chapter is not to document the code in detail, but to present an overview of how it works. This will perhaps ease the learning curve for someone who subsequently wishes to read the code.

## 71.1. Row Estimation Examples

The examples shown below use tables in the Postgres Pro regression test database. The outputs shown are taken from version 8.3. The behavior of earlier (or later) versions might vary. Note also that since `ANALYZE` uses random sampling while producing statistics, the results will change slightly after any new `ANALYZE`.

Let's start with a very simple query:

```
EXPLAIN SELECT * FROM tenk1;
```

QUERY PLAN

```
-----  
Seq Scan on tenk1  (cost=0.00..458.00 rows=10000 width=244)
```

How the planner determines the cardinality of `tenk1` is covered in [Section 14.2](#), but is repeated here for completeness. The number of pages and rows is looked up in `pg_class`:

```
SELECT relpages, reltuples FROM pg_class WHERE relname = 'tenk1';
```

```
relpages | reltuples  
-----+-----  
    358 |    10000
```

These numbers are current as of the last `VACUUM` or `ANALYZE` on the table. The planner then fetches the actual current number of pages in the table (this is a cheap operation, not requiring a table scan). If that is different from `relpages` then `reltuples` is scaled accordingly to arrive at a current number-of-rows estimate. In the example above, the value of `relpages` is up-to-date so the rows estimate is the same as `reltuples`.

Let's move on to an example with a range condition in its `WHERE` clause:

```
EXPLAIN SELECT * FROM tenk1 WHERE unique1 < 1000;
```

QUERY PLAN

```
-----  
Bitmap Heap Scan on tenk1  (cost=24.06..394.64 rows=1007 width=244)  
  Recheck Cond: (unique1 < 1000)  
    -> Bitmap Index Scan on tenk1_unique1  (cost=0.00..23.80 rows=1007 width=0)  
        Index Cond: (unique1 < 1000)
```

The planner examines the `WHERE` clause condition and looks up the selectivity function for the operator `<` in `pg_operator`. This is held in the column `oprrest`, and the entry in this case is `scalarlttsel`. The `scalarlttsel` function retrieves the histogram for `unique1` from `pg_statistic`. For manual queries it is more convenient to look in the simpler `pg_stats` view:

```
SELECT histogram_bounds FROM pg_stats  
WHERE tablename='tenk1' AND attname='unique1';
```

histogram\_bounds

```
-----  
{0, 993, 1997, 3050, 4040, 5036, 5957, 7057, 8029, 9016, 9995}
```

Next the fraction of the histogram occupied by “< 1000” is worked out. This is the selectivity. The histogram divides the range into equal frequency buckets, so all we have to do is locate the bucket that our value is in and count *part* of it and *all* of the ones before. The value 1000 is clearly in the second bucket (993–1997). Assuming a linear distribution of values inside each bucket, we can calculate the selectivity as:

```
selectivity = (1 + (1000 - bucket[2].min)/(bucket[2].max - bucket[2].min))/num_buckets
            = (1 + (1000 - 993)/(1997 - 993))/10
            = 0.100697
```

that is, one whole bucket plus a linear fraction of the second, divided by the number of buckets. The estimated number of rows can now be calculated as the product of the selectivity and the cardinality of `tenk1`:

```
rows = rel_cardinality * selectivity
      = 10000 * 0.100697
      = 1007   (rounding off)
```

Next let's consider an example with an equality condition in its `WHERE` clause:

```
EXPLAIN SELECT * FROM tenk1 WHERE stringu1 = 'CRAAAA';
```

#### QUERY PLAN

```
-----
Seq Scan on tenk1   (cost=0.00..483.00 rows=30 width=244)
  Filter: (stringu1 = 'CRAAAA'::name)
```

Again the planner examines the `WHERE` clause condition and looks up the selectivity function for `=`, which is `eqsel`. For equality estimation the histogram is not useful; instead the list of *most common values* (MCVs) is used to determine the selectivity. Let's have a look at the MCVs, with some additional columns that will be useful later:

```
SELECT null_frac, n_distinct, most_common_vals, most_common_freqs FROM pg_stats
WHERE tablename='tenk1' AND attname='stringu1';
```

```
null_frac          | 0
n_distinct         | 676
most_common_vals   | {EJAAAA,BBAAAA,CRAAAA,FCAAAA,FEAAAA,GSAAAA,
JOAAAA,MCAAAA,NAAAAA,WGAAAA}
most_common_freqs  | {0.00333333,0.003,0.003,0.003,0.003,0.003,0.003,0.003,0.003,0.003}
```

Since `CRAAAA` appears in the list of MCVs, the selectivity is merely the corresponding entry in the list of most common frequencies (MCFs):

```
selectivity = mcf[3]
            = 0.003
```

As before, the estimated number of rows is just the product of this with the cardinality of `tenk1`:

```
rows = 10000 * 0.003
      = 30
```

Now consider the same query, but with a constant that is not in the MCV list:

```
EXPLAIN SELECT * FROM tenk1 WHERE stringu1 = 'xxx';
```

#### QUERY PLAN

```
-----
Seq Scan on tenk1   (cost=0.00..483.00 rows=15 width=244)
  Filter: (stringu1 = 'xxx'::name)
```

This is quite a different problem: how to estimate the selectivity when the value is *not* in the MCV list. The approach is to use the fact that the value is not in the list, combined with the knowledge of the frequencies for all of the MCVs:

```
selectivity = (1 - sum(mvf))/(num_distinct - num_mcv)
            = (1 - (0.00333333 + 0.003 + 0.003 + 0.003 + 0.003 + 0.003 +
                    0.003 + 0.003 + 0.003 + 0.003))/(676 - 10)
            = 0.0014559
```

That is, add up all the frequencies for the MCVs and subtract them from one, then divide by the number of *other* distinct values. This amounts to assuming that the fraction of the column that is not any of the MCVs is evenly distributed among all the other distinct values. Notice that there are no null values so we don't have to worry about those (otherwise we'd subtract the null fraction from the numerator as well). The estimated number of rows is then calculated as usual:

```
rows = 10000 * 0.0014559
      = 15   (rounding off)
```

The previous example with `unique1 < 1000` was an oversimplification of what `scalarltsel` really does; now that we have seen an example of the use of MCVs, we can fill in some more detail. The example was correct as far as it went, because since `unique1` is a unique column it has no MCVs (obviously, no value is any more common than any other value). For a non-unique column, there will normally be both a histogram and an MCV list, and *the histogram does not include the portion of the column population represented by the MCVs*. We do things this way because it allows more precise estimation. In this situation `scalarltsel` directly applies the condition (e.g., “< 1000”) to each value of the MCV list, and adds up the frequencies of the MCVs for which the condition is true. This gives an exact estimate of the selectivity within the portion of the table that is MCVs. The histogram is then used in the same way as above to estimate the selectivity in the portion of the table that is not MCVs, and then the two numbers are combined to estimate the overall selectivity. For example, consider

```
EXPLAIN SELECT * FROM tenk1 WHERE stringu1 < 'IAAAAA';
```

#### QUERY PLAN

```
-----
Seq Scan on tenk1   (cost=0.00..483.00 rows=3077 width=244)
  Filter: (stringu1 < 'IAAAAA'::name)
```

We already saw the MCV information for `stringu1`, and here is its histogram:

```
SELECT histogram_bounds FROM pg_stats
WHERE tablename='tenk1' AND attname='stringu1';
```

#### histogram\_bounds

```
-----
{AAAAAA,CQAAAA,FRAAAA,IBAAAA,KRAAAA,NFAAAA,PSAAAA,SGAAAA,VAAAAA,XLAAAA,ZZAAAA}
```

Checking the MCV list, we find that the condition `stringu1 < 'IAAAAA'` is satisfied by the first six entries and not the last four, so the selectivity within the MCV part of the population is

```
selectivity = sum(relevant mvfs)
            = 0.00333333 + 0.003 + 0.003 + 0.003 + 0.003 + 0.003
            = 0.01833333
```

Summing all the MCFs also tells us that the total fraction of the population represented by MCVs is 0.03033333, and therefore the fraction represented by the histogram is 0.96966667 (again, there are no nulls, else we'd have to exclude them here). We can see that the value `IAAAAA` falls nearly at the end of the third histogram bucket. Using some rather cheesy assumptions about the frequency of different characters, the planner arrives at the estimate 0.298387 for the portion of the histogram population that is less than `IAAAAA`. We then combine the estimates for the MCV and non-MCV populations:

```
selectivity = mcv_selectivity + histogram_selectivity * histogram_fraction
            = 0.01833333 + 0.298387 * 0.96966667
            = 0.307669

rows        = 10000 * 0.307669
            = 3077   (rounding off)
```

In this particular example, the correction from the MCV list is fairly small, because the column distribution is actually quite flat (the statistics showing these particular values as being more common than others are mostly due to sampling error). In a more typical case where some values are significantly more common than others, this complicated process gives a useful improvement in accuracy because the selectivity for the most common values is found exactly.

Now let's consider a case with more than one condition in the `WHERE` clause:

```
EXPLAIN SELECT * FROM tenk1 WHERE unique1 < 1000 AND stringu1 = 'xxx';
```

QUERY PLAN

```
-----
Bitmap Heap Scan on tenk1  (cost=23.80..396.91 rows=1 width=244)
  Recheck Cond: (unique1 < 1000)
  Filter: (stringu1 = 'xxx'::name)
    -> Bitmap Index Scan on tenk1_unique1  (cost=0.00..23.80 rows=1007 width=0)
        Index Cond: (unique1 < 1000)
```

The planner assumes that the two conditions are independent, so that the individual selectivities of the clauses can be multiplied together:

```
selectivity = selectivity(unique1 < 1000) * selectivity(stringu1 = 'xxx')
              = 0.100697 * 0.0014559
              = 0.0001466

rows        = 10000 * 0.0001466
              = 1   (rounding off)
```

Notice that the number of rows estimated to be returned from the bitmap index scan reflects only the condition used with the index; this is important since it affects the cost estimate for the subsequent heap fetches.

Finally we will examine a query that involves a join:

```
EXPLAIN SELECT * FROM tenk1 t1, tenk2 t2
WHERE t1.unique1 < 50 AND t1.unique2 = t2.unique2;
```

QUERY PLAN

```
-----
Nested Loop  (cost=4.64..456.23 rows=50 width=488)
  -> Bitmap Heap Scan on tenk1 t1  (cost=4.64..142.17 rows=50 width=244)
      Recheck Cond: (unique1 < 50)
      -> Bitmap Index Scan on tenk1_unique1  (cost=0.00..4.63 rows=50 width=0)
          Index Cond: (unique1 < 50)
  -> Index Scan using tenk2_unique2 on tenk2 t2  (cost=0.00..6.27 rows=1 width=244)
      Index Cond: (unique2 = t1.unique2)
```

The restriction on `tenk1, unique1 < 50`, is evaluated before the nested-loop join. This is handled analogously to the previous range example. This time the value 50 falls into the first bucket of the `unique1` histogram:

```
selectivity = (0 + (50 - bucket[1].min)/(bucket[1].max - bucket[1].min))/num_buckets
              = (0 + (50 - 0)/(993 - 0))/10
              = 0.005035

rows        = 10000 * 0.005035
              = 50   (rounding off)
```

The restriction for the join is `t2.unique2 = t1.unique2`. The operator is just our familiar `=`, however the selectivity function is obtained from the `oprjoin` column of `pg_operator`, and is `eqjoinsel`. `eqjoinsel` looks up the statistical information for both `tenk2` and `tenk1`:

```
SELECT tablename, null_frac,n_distinct, most_common_vals FROM pg_stats
```

```
WHERE tablename IN ('tenk1', 'tenk2') AND attname='unique2';
```

| tablename | null_frac | n_distinct | most_common_vals |
|-----------|-----------|------------|------------------|
| tenk1     | 0         | -1         |                  |
| tenk2     | 0         | -1         |                  |

In this case there is no MCV information for `unique2` because all the values appear to be unique, so we use an algorithm that relies only on the number of distinct values for both relations together with their null fractions:

```
selectivity = (1 - null_frac1) * (1 - null_frac2) * min(1/num_distinct1, 1/
num_distinct2)
             = (1 - 0) * (1 - 0) / max(10000, 10000)
             = 0.0001
```

This is, subtract the null fraction from one for each of the relations, and divide by the maximum of the numbers of distinct values. The number of rows that the join is likely to emit is calculated as the cardinality of the Cartesian product of the two inputs, multiplied by the selectivity:

```
rows = (outer_cardinality * inner_cardinality) * selectivity
      = (50 * 10000) * 0.0001
      = 50
```

Had there been MCV lists for the two columns, `eqjoinse1` would have used direct comparison of the MCV lists to determine the join selectivity within the part of the column populations represented by the MCVs. The estimate for the remainder of the populations follows the same approach shown here.

Notice that we showed `inner_cardinality` as 10000, that is, the unmodified size of `tenk2`. It might appear from inspection of the `EXPLAIN` output that the estimate of join rows comes from  $50 * 1$ , that is, the number of outer rows times the estimated number of rows obtained by each inner index scan on `tenk2`. But this is not the case: the join relation size is estimated before any particular join plan has been considered. If everything is working well then the two ways of estimating the join size will produce about the same answer, but due to round-off error and other factors they sometimes diverge significantly.

## 71.2. Multivariate Statistics Examples

### 71.2.1. Functional Dependencies

Multivariate correlation can be demonstrated with a very simple data set — a table with two columns, both containing the same values:

```
CREATE TABLE t (a INT, b INT);
INSERT INTO t SELECT i % 100, i % 100 FROM generate_series(1, 10000) s(i);
ANALYZE t;
```

As explained in [Section 14.2](#), the planner can determine cardinality of `t` using the number of pages and rows obtained from `pg_class`:

```
SELECT relpages, reltuples FROM pg_class WHERE relname = 't';
```

| relpages | reltuples |
|----------|-----------|
| 45       | 10000     |

The data distribution is very simple; there are only 100 distinct values in each column, uniformly distributed.

The following example shows the result of estimating a `WHERE` condition on the `a` column:

```
EXPLAIN (ANALYZE, TIMING OFF) SELECT * FROM t WHERE a = 1;
QUERY PLAN
```

```
Seq Scan on t (cost=0.00..170.00 rows=100 width=8) (actual rows=100 loops=1)
  Filter: (a = 1)
  Rows Removed by Filter: 9900
```

The planner examines the condition and determines the selectivity of this clause to be 1%. By comparing this estimate and the actual number of rows, we see that the estimate is very accurate (in fact exact, as the table is very small). Changing the `WHERE` condition to use the `b` column, an identical plan is generated. But observe what happens if we apply the same condition on both columns, combining them with `AND`:

```
EXPLAIN (ANALYZE, TIMING OFF) SELECT * FROM t WHERE a = 1 AND b = 1;
                                QUERY PLAN
```

```
-----
Seq Scan on t (cost=0.00..195.00 rows=1 width=8) (actual rows=100 loops=1)
  Filter: ((a = 1) AND (b = 1))
  Rows Removed by Filter: 9900
```

The planner estimates the selectivity for each condition individually, arriving at the same 1% estimates as above. Then it assumes that the conditions are independent, and so it multiplies their selectivities, producing a final selectivity estimate of just 0.01%. This is a significant underestimate, as the actual number of rows matching the conditions (100) is two orders of magnitude higher.

This problem can be fixed by creating a statistics object that directs `ANALYZE` to calculate functional-dependency multivariate statistics on the two columns:

```
CREATE STATISTICS stts (dependencies) ON a, b FROM t;
ANALYZE t;
EXPLAIN (ANALYZE, TIMING OFF) SELECT * FROM t WHERE a = 1 AND b = 1;
                                QUERY PLAN
```

```
-----
Seq Scan on t (cost=0.00..195.00 rows=100 width=8) (actual rows=100 loops=1)
  Filter: ((a = 1) AND (b = 1))
  Rows Removed by Filter: 9900
```

## 71.2.2. Multivariate N-Distinct Counts

A similar problem occurs with estimation of the cardinality of sets of multiple columns, such as the number of groups that would be generated by a `GROUP BY` clause. When `GROUP BY` lists a single column, the `n-distinct` estimate (which is visible as the estimated number of rows returned by the `HashAggregate` node) is very accurate:

```
EXPLAIN (ANALYZE, TIMING OFF) SELECT COUNT(*) FROM t GROUP BY a;
                                QUERY PLAN
```

```
-----
HashAggregate (cost=195.00..196.00 rows=100 width=12) (actual rows=100 loops=1)
  Group Key: a
    -> Seq Scan on t (cost=0.00..145.00 rows=10000 width=4) (actual rows=10000
loops=1)
```

But without multivariate statistics, the estimate for the number of groups in a query with two columns in `GROUP BY`, as in the following example, is off by an order of magnitude:

```
EXPLAIN (ANALYZE, TIMING OFF) SELECT COUNT(*) FROM t GROUP BY a, b;
                                QUERY PLAN
```

```
-----
HashAggregate (cost=220.00..230.00 rows=1000 width=16) (actual rows=100 loops=1)
  Group Key: a, b
    -> Seq Scan on t (cost=0.00..145.00 rows=10000 width=8) (actual rows=10000
loops=1)
```

By redefining the statistics object to include n-distinct counts for the two columns, the estimate is much improved:

```
DROP STATISTICS stts;
CREATE STATISTICS stts (dependencies, ndistinct) ON a, b FROM t;
ANALYZE t;
EXPLAIN (ANALYZE, TIMING OFF) SELECT COUNT(*) FROM t GROUP BY a, b;
                                QUERY PLAN
-----
HashAggregate  (cost=220.00..221.00 rows=100 width=16) (actual rows=100 loops=1)
  Group Key: a, b
    -> Seq Scan on t  (cost=0.00..145.00 rows=10000 width=8) (actual rows=10000
        loops=1)
```

### 71.2.3. MCV Lists

As explained in [Section 71.2.1](#), functional dependencies are very cheap and efficient type of statistics, but their main limitation is their global nature (only tracking dependencies at the column level, not between individual column values).

This section introduces multivariate variant of MCV (most-common values) lists, a straightforward extension of the per-column statistics described in [Section 71.1](#). These statistics address the limitation by storing individual values, but it is naturally more expensive, both in terms of building the statistics in `ANALYZE`, storage and planning time.

Let's look at the query from [Section 71.2.1](#) again, but this time with a MCV list created on the same set of columns (be sure to drop the functional dependencies, to make sure the planner uses the newly created statistics).

```
DROP STATISTICS stts;
CREATE STATISTICS stts2 (mcv) ON a, b FROM t;
ANALYZE t;
EXPLAIN (ANALYZE, TIMING OFF) SELECT * FROM t WHERE a = 1 AND b = 1;
                                QUERY PLAN
-----
Seq Scan on t  (cost=0.00..195.00 rows=100 width=8) (actual rows=100 loops=1)
  Filter: ((a = 1) AND (b = 1))
  Rows Removed by Filter: 9900
```

The estimate is as accurate as with the functional dependencies, mostly thanks to the table being fairly small and having a simple distribution with a low number of distinct values. Before looking at the second query, which was not handled by functional dependencies particularly well, let's inspect the MCV list a bit.

Inspecting the MCV list is possible using `pg_mcv_list_items` set-returning function.

```
SELECT m.* FROM pg_statistic_ext join pg_statistic_ext_data on (oid = stxoid),
        pg_mcv_list_items(stxmcv) m WHERE stxname = 'stts2';
```

| index | values   | nulls | frequency | base_frequency |
|-------|----------|-------|-----------|----------------|
| 0     | {0, 0}   | {f,f} | 0.01      | 0.0001         |
| 1     | {1, 1}   | {f,f} | 0.01      | 0.0001         |
| ...   |          |       |           |                |
| 49    | {49, 49} | {f,f} | 0.01      | 0.0001         |
| 50    | {50, 50} | {f,f} | 0.01      | 0.0001         |
| ...   |          |       |           |                |
| 97    | {97, 97} | {f,f} | 0.01      | 0.0001         |
| 98    | {98, 98} | {f,f} | 0.01      | 0.0001         |
| 99    | {99, 99} | {f,f} | 0.01      | 0.0001         |

(100 rows)

This confirms there are 100 distinct combinations in the two columns, and all of them are about equally likely (1% frequency for each one). The base frequency is the frequency computed from per-column statistics, as if there were no multi-column statistics. Had there been any null values in either of the columns, this would be identified in the `nulls` column.

When estimating the selectivity, the planner applies all the conditions on items in the MCV list, and then sums the frequencies of the matching ones.

Compared to functional dependencies, MCV lists have two major advantages. Firstly, the list stores actual values, making it possible to decide which combinations are compatible.

```
EXPLAIN (ANALYZE, TIMING OFF) SELECT * FROM t WHERE a = 1 AND b = 10;
                                QUERY PLAN
```

```
-----
Seq Scan on t  (cost=0.00..195.00 rows=1 width=8) (actual rows=0 loops=1)
  Filter: ((a = 1) AND (b = 10))
  Rows Removed by Filter: 10000
```

Secondly, MCV lists handle a wider range of clause types, not just equality clauses like functional dependencies. For example, consider the following range query for the same table:

```
EXPLAIN (ANALYZE, TIMING OFF) SELECT * FROM t WHERE a <= 49 AND b > 49;
                                QUERY PLAN
```

```
-----
Seq Scan on t  (cost=0.00..195.00 rows=1 width=8) (actual rows=0 loops=1)
  Filter: ((a <= 49) AND (b > 49))
  Rows Removed by Filter: 10000
```

## 71.3. Planner Statistics and Security

Access to the table `pg_statistic` is restricted to superusers, so that ordinary users cannot learn about the contents of the tables of other users from it. Some selectivity estimation functions will use a user-provided operator (either the operator appearing in the query or a related operator) to analyze the stored statistics. For example, in order to determine whether a stored most common value is applicable, the selectivity estimator will have to run the appropriate `=` operator to compare the constant in the query to the stored value. Thus the data in `pg_statistic` is potentially passed to user-defined operators. An appropriately crafted operator can intentionally leak the passed operands (for example, by logging them or writing them to a different table), or accidentally leak them by showing their values in error messages, in either case possibly exposing data from `pg_statistic` to a user who should not be able to see it.

In order to prevent this, the following applies to all built-in selectivity estimation functions. When planning a query, in order to be able to use stored statistics, the current user must either have `SELECT` privilege on the table or the involved columns, or the operator used must be `LEAKPROOF` (more accurately, the function that the operator is based on). If not, then the selectivity estimator will behave as if no statistics are available, and the planner will proceed with default or fall-back assumptions.

If a user does not have the required privilege on the table or columns, then in many cases the query will ultimately receive a permission-denied error, in which case this mechanism is invisible in practice. But if the user is reading from a security-barrier view, then the planner might wish to check the statistics of an underlying table that is otherwise inaccessible to the user. In that case, the operator should be leak-proof or the statistics will not be used. There is no direct feedback about that, except that the plan might be suboptimal. If one suspects that this is the case, one could try running the query as a more privileged user, to see if a different plan results.

This restriction applies only to cases where the planner would need to execute a user-defined operator on one or more values from `pg_statistic`. Thus the planner is permitted to use generic statistical information, such as the fraction of null values or the number of distinct values in a column, regardless of access privileges.

Selectivity estimation functions contained in third-party extensions that potentially operate on statistics with user-defined operators should follow the same security rules.

---

# Chapter 72. Backup Manifest Format

The backup manifest generated by [pg\\_basebackup](#) is primarily intended to permit the backup to be verified using [pg\\_verifybackup](#). However, it is also possible for other tools to read the backup manifest file and use the information contained therein for their own purposes. To that end, this chapter describes the format of the backup manifest file.

A backup manifest is a JSON document encoded as UTF-8. (Although in general JSON documents are required to be Unicode, PostgreSQL permits the `json` and `jsonb` data types to be used with any supported server encoding. There is no similar exception for backup manifests.) The JSON document is always an object; the keys that are present in this object are described in the next section.

## 72.1. Backup Manifest Top-level Object

The backup manifest JSON document contains the following keys.

`PostgreSQL-Backup-Manifest-Version`

The associated value is always the integer 1.

`Files`

The associated value is always a list of objects, each describing one file that is present in the backup. No entries are present in this list for the WAL files that are needed in order to use the backup, or for the backup manifest itself. The structure of each object in the list is described in [Section 72.2](#).

`WAL-Ranges`

The associated value is always a list of objects, each describing a range of WAL records that must be readable from a particular timeline in order to make use of the backup. The structure of these objects is further described in [Section 72.3](#).

`Manifest-Checksum`

This key is always present on the last line of the backup manifest file. The associated value is a SHA256 checksum of all the preceding lines. We use a fixed checksum method here to make it possible for clients to do incremental parsing of the manifest. While a SHA256 checksum is significantly more expensive than a CRC32C checksum, the manifest should normally be small enough that the extra computation won't matter very much.

## 72.2. Backup Manifest File Object

The object which describes a single file contains either a `Path` key or an `Encoded-Path` key. Normally, the `Path` key will be present. The associated string value is the path of the file relative to the root of the backup directory. Files located in a user-defined tablespace will have paths whose first two components are `pg_tblspc` and the OID of the tablespace. If the path is not a string that is legal in UTF-8, or if the user requests that encoded paths be used for all files, then the `Encoded-Path` key will be present instead. This stores the same data, but it is encoded as a string of hexadecimal digits. Each pair of hexadecimal digits in the string represents a single octet.

The following two keys are always present:

`Size`

The expected size of this file, as an integer.

`Last-Modified`

The last modification time of the file as reported by the server at the time of the backup. Unlike the other fields stored in the backup, this field is not used by [pg\\_verifybackup](#). It is included only for informational purposes.

If the backup was taken with file checksums enabled, the following keys will be present:

`Checksum-Algorithm`

The checksum algorithm used to compute a checksum for this file. Currently, this will be the same for every file in the backup manifest, but this may change in future releases. At present, the supported checksum algorithms are `CRC32C`, `SHA224`, `SHA256`, `SHA384`, and `SHA512`.

`Checksum`

The checksum computed for this file, stored as a series of hexadecimal characters, two for each byte of the checksum.

## 72.3. Backup Manifest WAL Range Object

The object which describes a WAL range always has three keys:

`Timeline`

The timeline for this range of WAL records, as an integer.

`Start-LSN`

The LSN at which replay must begin on the indicated timeline in order to make use of this backup. The LSN is stored in the format normally used by PostgreSQL; that is, it is a string consisting of two strings of hexadecimal characters, each with a length of between 1 and 8, separated by a slash.

`End-LSN`

The earliest LSN at which replay on the indicated timeline may end when making use of this backup. This is stored in the same format as `Start-LSN`.

Ordinarily, there will be only a single WAL range. However, if a backup is taken from a standby which switches timelines during the backup due to an upstream promotion, it is possible for multiple ranges to be present, each with a different timeline. There will never be multiple WAL ranges present for the same timeline.

---

## **Part VIII. Appendixes**

---

# Appendix A. Postgres Pro Error Codes

All messages emitted by the Postgres Pro server are assigned five-character error codes that follow the SQL standard's conventions for "SQLSTATE" codes. Applications that need to know which error condition has occurred should usually test the error code, rather than looking at the textual error message. The error codes are less likely to change across Postgres Pro releases, and also are not subject to change due to localization of error messages. Note that some, but not all, of the error codes produced by Postgres Pro are defined by the SQL standard; some additional error codes for conditions not defined by the standard have been invented or borrowed from other databases.

According to the standard, the first two characters of an error code denote a class of errors, while the last three characters indicate a specific condition within that class. Thus, an application that does not recognize the specific error code might still be able to infer what to do from the error class.

**Table A.1** lists all the error codes defined in Postgres Pro Enterprise 14.20.1. (Some are not actually used at present, but are defined by the SQL standard.) The error classes are also shown. For each error class there is a "standard" error code having the last three characters 000. This code is used only for error conditions that fall within the class but do not have any more-specific code assigned.

The symbol shown in the column "Condition Name" is the condition name to use in PL/pgSQL. Condition names can be written in either upper or lower case. (Note that PL/pgSQL does not recognize warning, as opposed to error, condition names; those are classes 00, 01, and 02.)

For some types of errors, the server reports the name of a database object (a table, table column, data type, or constraint) associated with the error; for example, the name of the unique constraint that caused a `unique_violation` error. Such names are supplied in separate fields of the error report message so that applications need not try to extract them from the possibly-localized human-readable text of the message. As of PostgreSQL 9.3, complete coverage for this feature exists only for errors in SQLSTATE class 23 (integrity constraint violation), but this is likely to be expanded in future.

**Table A.1. Postgres Pro Error Codes**

| Error Code                                                                    | Condition Name                             |
|-------------------------------------------------------------------------------|--------------------------------------------|
| <b>Class 00 — Successful Completion</b>                                       |                                            |
| 00000                                                                         | successful_completion                      |
| <b>Class 01 — Warning</b>                                                     |                                            |
| 01000                                                                         | warning                                    |
| 0100C                                                                         | dynamic_result_sets_returned               |
| 01008                                                                         | implicit_zero_bit_padding                  |
| 01003                                                                         | null_value_eliminated_in_set_function      |
| 01007                                                                         | privilege_not_granted                      |
| 01006                                                                         | privilege_not_revoked                      |
| 01004                                                                         | string_data_right_truncation               |
| 01P01                                                                         | deprecated_feature                         |
| <b>Class 02 — No Data (this is also a warning class per the SQL standard)</b> |                                            |
| 02000                                                                         | no_data                                    |
| 02001                                                                         | no_additional_dynamic_result_sets_returned |
| <b>Class 03 — SQL Statement Not Yet Complete</b>                              |                                            |
| 03000                                                                         | sql_statement_not_yet_complete             |
| <b>Class 08 — Connection Exception</b>                                        |                                            |
| 08000                                                                         | connection_exception                       |

| Error Code                                       | Condition Name                                      |

# Appendix B. Date/Time Support

Postgres Pro uses an internal heuristic parser for all date/time input support. Dates and times are input as strings, and are broken up into distinct fields with a preliminary determination of what kind of information can be in the field. Each field is interpreted and either assigned a numeric value, ignored, or rejected. The parser contains internal lookup tables for all textual fields, including months, days of the week, and time zones.

This appendix includes information on the content of these lookup tables and describes the steps used by the parser to decode dates and times.

## B.1. Date/Time Input Interpretation

Date/time input strings are decoded using the following procedure.

1. Break the input string into tokens and categorize each token as a string, time, time zone, or number.
  - a. If the numeric token contains a colon (:), this is a time string. Include all subsequent digits and colons.
  - b. If the numeric token contains a dash (-), slash (/), or two or more dots (.), this is a date string which might have a text month. If a date token has already been seen, it is instead interpreted as a time zone name (e.g., `America/New_York`).
  - c. If the token is numeric only, then it is either a single field or an ISO 8601 concatenated date (e.g., `19990113` for January 13, 1999) or time (e.g., `141516` for 14:15:16).
  - d. If the token starts with a plus (+) or minus (-), then it is either a numeric time zone or a special field.
2. If the token is an alphabetic string, match up with possible strings:
  - a. See if the token matches any known time zone abbreviation. These abbreviations are supplied by the configuration file described in [Section B.4](#).
  - b. If not found, search an internal table to match the token as either a special string (e.g., `today`), day (e.g., `Thursday`), month (e.g., `January`), or noise word (e.g., `at`, `on`).
  - c. If still not found, throw an error.
3. When the token is a number or number field:
  - a. If there are eight or six digits, and if no other date fields have been previously read, then interpret as a “concatenated date” (e.g., `19990118` or `990118`). The interpretation is `YYYYMMDD` or `YYMMDD`.
  - b. If the token is three digits and a year has already been read, then interpret as day of year.
  - c. If four or six digits and a year has already been read, then interpret as a time (`HHMM` or `HHMMSS`).
  - d. If three or more digits and no date fields have yet been found, interpret as a year (this forces `yy-mm-dd` ordering of the remaining date fields).
  - e. Otherwise the date field ordering is assumed to follow the `DateStyle` setting: `mm-dd-yy`, `dd-mm-yy`, or `yy-mm-dd`. Throw an error if a month or day field is found to be out of range.
4. If BC has been specified, negate the year and add one for internal storage. (There is no year zero in the Gregorian calendar, so numerically 1 BC becomes year zero.)
5. If BC was not specified, and if the year field was two digits in length, then adjust the year to four digits. If the field is less than 70, then add 2000, otherwise add 1900.

**Tip**

Gregorian years AD 1-99 can be entered by using 4 digits with leading zeros (e.g., 0099 is AD 99).

## B.2. Handling of Invalid or Ambiguous Timestamps

Ordinarily, if a date/time string is syntactically valid but contains out-of-range field values, an error will be thrown. For example, input specifying the 31st of February will be rejected.

During a daylight-savings-time transition, it is possible for a seemingly valid timestamp string to represent a nonexistent or ambiguous timestamp. Such cases are not rejected; the ambiguity is resolved by determining which UTC offset to apply. For example, supposing that the [TimeZone](#) parameter is set to `America/New_York`, consider

```
=> SELECT '2018-03-11 02:30'::timestampz;
       timestampz
-----
2018-03-11 03:30:00-04
(1 row)
```

Because that day was a spring-forward transition date in that time zone, there was no civil time instant 2:30AM; clocks jumped forward from 2AM EST to 3AM EDT. Postgres Pro interprets the given time as if it were standard time (UTC-5), which then renders as 3:30AM EDT (UTC-4).

Conversely, consider the behavior during a fall-back transition:

```
=> SELECT '2018-11-04 01:30'::timestampz;
       timestampz
-----
2018-11-04 01:30:00-05
(1 row)
```

On that date, there were two possible interpretations of 1:30AM; there was 1:30AM EDT, and then an hour later after clocks jumped back from 2AM EDT to 1AM EST, there was 1:30AM EST. Again, Postgres Pro interprets the given time as if it were standard time (UTC-5). We can force the other interpretation by specifying daylight-savings time:

```
=> SELECT '2018-11-04 01:30 EDT'::timestampz;
       timestampz
-----
2018-11-04 01:30:00-04
(1 row)
```

The precise rule that is applied in such cases is that an invalid timestamp that appears to fall within a jump-forward daylight savings transition is assigned the UTC offset that prevailed in the time zone just before the transition, while an ambiguous timestamp that could fall on either side of a jump-back transition is assigned the UTC offset that prevailed just after the transition. In most time zones this is equivalent to saying that “the standard-time interpretation is preferred when in doubt”.

In all cases, the UTC offset associated with a timestamp can be specified explicitly, using either a numeric UTC offset or a time zone abbreviation that corresponds to a fixed UTC offset. The rule just given applies only when it is necessary to infer a UTC offset for a time zone in which the offset varies.

## B.3. Date/Time Key Words

[Table B.1](#) shows the tokens that are recognized as names of months.

**Table B.1. Month Names**

| Month     | Abbreviations |
|-----------|---------------|
| January   | Jan           |
| February  | Feb           |
| March     | Mar           |
| April     | Apr           |
| May       |               |
| June      | Jun           |
| July      | Jul           |
| August    | Aug           |
| September | Sep, Sept     |
| October   | Oct           |
| November  | Nov           |
| December  | Dec           |

Table B.2 shows the tokens that are recognized as names of days of the week.

**Table B.2. Day of the Week Names**

| Day       | Abbreviations    |
|-----------|------------------|
| Sunday    | Sun              |
| Monday    | Mon              |
| Tuesday   | Tue, Tues        |
| Wednesday | Wed, Weds        |
| Thursday  | Thu, Thur, Thurs |
| Friday    | Fri              |
| Saturday  | Sat              |

Table B.3 shows the tokens that serve various modifier purposes.

**Table B.3. Date/Time Field Modifiers**

| Identifier    | Description               |
|---------------|---------------------------|
| AM            | Time is before 12:00      |
| AT            | Ignored                   |
| JULIAN, JD, J | Next field is Julian Date |
| ON            | Ignored                   |
| PM            | Time is on or after 12:00 |
| T             | Next field is time        |

## B.4. Date/Time Configuration Files

Since timezone abbreviations are not well standardized, Postgres Pro provides a means to customize the set of abbreviations accepted by the server. The [timezone\\_abbreviations](#) run-time parameter determines the active set of abbreviations. While this parameter can be altered by any database user, the possible values for it are under the control of the database administrator — they are in fact names of configuration files stored in `.../share/timezonesets/` of the installation directory. By adding or altering files in that directory, the administrator can set local policy for timezone abbreviations.

`timezone_abbreviations` can be set to any file name found in `.../share/zoneinfo/`, if the file's name is entirely alphabetic. (The prohibition against non-alphabetic characters in `timezone_abbreviations` prevents reading files outside the intended directory, as well as reading editor backup files and other extraneous files.)

A timezone abbreviation file can contain blank lines and comments beginning with `#`. Non-comment lines must have one of these formats:

```
zone_abbreviation offset
zone_abbreviation offset D
zone_abbreviation time_zone_name
@INCLUDE file_name
@OVERRIDE
```

A *zone\_abbreviation* is just the abbreviation being defined. An *offset* is an integer giving the equivalent offset in seconds from UTC, positive being east from Greenwich and negative being west. For example, -18000 would be five hours west of Greenwich, or North American east coast standard time. `D` indicates that the zone name represents local daylight-savings time rather than standard time.

Alternatively, a *time\_zone\_name* can be given, referencing a zone name defined in the IANA timezone database. The zone's definition is consulted to see whether the abbreviation is or has been in use in that zone, and if so, the appropriate meaning is used — that is, the meaning that was currently in use at the timestamp whose value is being determined, or the meaning in use immediately before that if it wasn't current at that time, or the oldest meaning if it was used only after that time. This behavior is essential for dealing with abbreviations whose meaning has historically varied. It is also allowed to define an abbreviation in terms of a zone name in which that abbreviation does not appear; then using the abbreviation is just equivalent to writing out the zone name.

### Tip

Using a simple integer *offset* is preferred when defining an abbreviation whose offset from UTC has never changed, as such abbreviations are much cheaper to process than those that require consulting a time zone definition.

The `@INCLUDE` syntax allows inclusion of another file in the `.../share/zoneinfo/` directory. Inclusion can be nested, to a limited depth.

The `@OVERRIDE` syntax indicates that subsequent entries in the file can override previous entries (typically, entries obtained from included files). Without this, conflicting definitions of the same timezone abbreviation are considered an error.

In an unmodified installation, the file `Default` contains all the non-conflicting time zone abbreviations for most of the world. Additional files `Australia` and `India` are provided for those regions: these files first include the `Default` file and then add or modify abbreviations as needed.

For reference purposes, a standard installation also contains files `Africa.txt`, `America.txt`, etc, containing information about every time zone abbreviation known to be in use according to the IANA timezone database. The zone name definitions found in these files can be copied and pasted into a custom configuration file as needed. Note that these files cannot be directly referenced as `timezone_abbreviations` settings, because of the dot embedded in their names.

### Note

If an error occurs while reading the time zone abbreviation set, no new value is applied and the old set is kept. If the error occurs while starting the database, startup fails.

**Caution**

Time zone abbreviations defined in the configuration file override non-timezone meanings built into Postgres Pro. For example, the `Australia` configuration file defines `SAT` (for South Australian Standard Time). When this file is active, `SAT` will not be recognized as an abbreviation for Saturday.

**Caution**

If you modify files in `.../share/timezonesets/`, it is up to you to make backups — a normal database dump will not include this directory.

## B.5. POSIX Time Zone Specifications

Postgres Pro can accept time zone specifications that are written according to the POSIX standard's rules for the `TZ` environment variable. POSIX time zone specifications are inadequate to deal with the complexity of real-world time zone history, but there are sometimes reasons to use them.

A POSIX time zone specification has the form

```
STD offset [ DST [ dstoffset ] [ , rule ] ]
```

(For readability, we show spaces between the fields, but spaces should not be used in practice.) The fields are:

- *STD* is the zone abbreviation to be used for standard time.
- *offset* is the zone's standard-time offset from UTC.
- *DST* is the zone abbreviation to be used for daylight-savings time. If this field and the following ones are omitted, the zone uses a fixed UTC offset with no daylight-savings rule.
- *dstoffset* is the daylight-savings offset from UTC. This field is typically omitted, since it defaults to one hour less than the standard-time *offset*, which is usually the right thing.
- *rule* defines the rule for when daylight savings is in effect, as described below.

In this syntax, a zone abbreviation can be a string of letters, such as `EST`, or an arbitrary string surrounded by angle brackets, such as `<UTC-05>`. Note that the zone abbreviations given here are only used for output, and even then only in some timestamp output formats. The zone abbreviations recognized in timestamp input are determined as explained in [Section B.4](#).

The offset fields specify the hours, and optionally minutes and seconds, difference from UTC. They have the format `hh[:mm[:ss]]` optionally with a leading sign (+ or -). The positive sign is used for zones west of Greenwich. (Note that this is the opposite of the ISO-8601 sign convention used elsewhere in Postgres Pro.) *hh* can have one or two digits; *mm* and *ss* (if used) must have two.

The daylight-savings transition *rule* has the format

```
dstdate [ / dsttime ] , stddate [ / stdtime ]
```

(As before, spaces should not be included in practice.) The *dstdate* and *dsttime* fields define when daylight-savings time starts, while *stddate* and *stdtime* define when standard time starts. (In some cases, notably in zones south of the equator, the former might be later in the year than the latter.) The date fields have one of these formats:

*n*

A plain integer denotes a day of the year, counting from zero to 364, or to 365 in leap years.

*Jn*

In this form, *n* counts from 1 to 365, and February 29 is not counted even if it is present. (Thus, a transition occurring on February 29 could not be specified this way. However, days after February

have the same numbers whether it's a leap year or not, so that this form is usually more useful than the plain-integer form for transitions on fixed dates.)

`Mm.n.d`

This form specifies a transition that always happens during the same month and on the same day of the week. *m* identifies the month, from 1 to 12. *n* specifies the *n*'th occurrence of the weekday identified by *d*. *n* is a number between 1 and 4, or 5 meaning the last occurrence of that weekday in the month (which could be the fourth or the fifth). *d* is a number between 0 and 6, with 0 indicating Sunday. For example, `M3.2.0` means “the second Sunday in March”.

### Note

The `M` format is sufficient to describe many common daylight-savings transition laws. But note that none of these variants can deal with daylight-savings law changes, so in practice the historical data stored for named time zones (in the IANA time zone database) is necessary to interpret past time stamps correctly.

The time fields in a transition rule have the same format as the offset fields described previously, except that they cannot contain signs. They define the current local time at which the change to the other time occurs. If omitted, they default to `02:00:00`.

If a daylight-savings abbreviation is given but the transition *rule* field is omitted, the fallback behavior is to use the rule `M3.2.0,M11.1.0`, which corresponds to USA practice as of 2020 (that is, spring forward on the second Sunday of March, fall back on the first Sunday of November, both transitions occurring at 2AM prevailing time). Note that this rule does not give correct USA transition dates for years before 2007.

As an example, `CET-1CEST,M3.5.0,M10.5.0/3` describes current (as of 2020) timekeeping practice in Paris. This specification says that standard time has the abbreviation `CET` and is one hour ahead (east) of UTC; daylight savings time has the abbreviation `CEST` and is implicitly two hours ahead of UTC; daylight savings time begins on the last Sunday in March at 2AM CET and ends on the last Sunday in October at 3AM CEST.

The four timezone names `EST5EDT`, `CST6CDT`, `MST7MDT`, and `PST8PDT` look like they are POSIX zone specifications. However, they actually are treated as named time zones because (for historical reasons) there are files by those names in the IANA time zone database. The practical implication of this is that these zone names will produce valid historical USA daylight-savings transitions, even when a plain POSIX specification would not.

One should be wary that it is easy to misspell a POSIX-style time zone specification, since there is no check on the reasonableness of the zone abbreviation(s). For example, `SET TIMEZONE TO FOOBAR0` will work, leaving the system effectively using a rather peculiar abbreviation for UTC.

## B.6. History of Units

The SQL standard states that “Within the definition of a ‘datetime literal’, the ‘datetime values’ are constrained by the natural rules for dates and times according to the Gregorian calendar”. Postgres Pro follows the SQL standard's lead by counting dates exclusively in the Gregorian calendar, even for years before that calendar was in use. This rule is known as the *proleptic Gregorian calendar*.

The Julian calendar was introduced by Julius Caesar in 45 BC. It was in common use in the Western world until the year 1582, when countries started changing to the Gregorian calendar. In the Julian calendar, the tropical year is approximated as  $365 \frac{1}{4}$  days = 365.25 days. This gives an error of about 1 day in 128 years.

The accumulating calendar error prompted Pope Gregory XIII to reform the calendar in accordance with instructions from the Council of Trent. In the Gregorian calendar, the tropical year is approximated as

$365 + 97 / 400$  days = 365.2425 days. Thus it takes approximately 3300 years for the tropical year to shift one day with respect to the Gregorian calendar.

The approximation  $365+97/400$  is achieved by having 97 leap years every 400 years, using the following rules:

Every year divisible by 4 is a leap year.

However, every year divisible by 100 is not a leap year.

However, every year divisible by 400 is a leap year after all.

So, 1700, 1800, 1900, 2100, and 2200 are not leap years. But 1600, 2000, and 2400 are leap years. By contrast, in the older Julian calendar all years divisible by 4 are leap years.

The papal bull of February 1582 decreed that 10 days should be dropped from October 1582 so that 15 October should follow immediately after 4 October. This was observed in Italy, Poland, Portugal, and Spain. Other Catholic countries followed shortly after, but Protestant countries were reluctant to change, and the Greek Orthodox countries didn't change until the start of the 20th century. The reform was observed by Great Britain and its dominions (including what is now the USA) in 1752. Thus 2 September 1752 was followed by 14 September 1752. This is why Unix systems that have the `cal` program produce the following:

```
$ cal 9 1752
    September 1752
S  M Tu  W Th  F  S
      1  2 14 15 16
17 18 19 20 21 22 23
24 25 26 27 28 29 30
```

But, of course, this calendar is only valid for Great Britain and dominions, not other places. Since it would be difficult and confusing to try to track the actual calendars that were in use in various places at various times, Postgres Pro does not try, but rather follows the Gregorian calendar rules for all dates, even though this method is not historically accurate.

Different calendars have been developed in various parts of the world, many predating the Gregorian system. For example, the beginnings of the Chinese calendar can be traced back to the 14th century BC. Legend has it that the Emperor Huangdi invented that calendar in 2637 BC. The People's Republic of China uses the Gregorian calendar for civil purposes. The Chinese calendar is used for determining festivals.

## B.7. Julian Dates

The *Julian Date* system is a method for numbering days. It is unrelated to the Julian calendar, though it is confusingly named similarly to that calendar. The Julian Date system was invented by the French scholar Joseph Justus Scaliger (1540-1609) and probably takes its name from Scaliger's father, the Italian scholar Julius Caesar Scaliger (1484-1558).

In the Julian Date system, each day has a sequential number, starting from JD 0 (which is sometimes called *the* Julian Date). JD 0 corresponds to 1 January 4713 BC in the Julian calendar, or 24 November 4714 BC in the Gregorian calendar. Julian Date counting is most often used by astronomers for labeling their nightly observations, and therefore a date runs from noon UTC to the next noon UTC, rather than from midnight to midnight: JD 0 designates the 24 hours from noon UTC on 24 November 4714 BC to noon UTC on 25 November 4714 BC.

Although Postgres Pro supports Julian Date notation for input and output of dates (and also uses Julian dates for some internal datetime calculations), it does not observe the nicety of having dates run from noon to noon. Postgres Pro treats a Julian Date as running from local midnight to local midnight, the same as a normal date.

This definition does, however, provide a way to obtain the astronomical definition when you need it: do the arithmetic in time zone `UTC+12`. For example,

-----  
extract

```
(1 row)
```

-----  
extract

```
(1 row)
```

extract

```
(1 row)
```

---

# Appendix C. SQL Key Words

[Table C.1](#) lists all tokens that are key words in the SQL standard and in Postgres Pro Enterprise 14.20.1. Background information can be found in [Section 4.1.1](#). (For space reasons, only the latest two versions of the SQL standard, and SQL-92 for historical comparison, are included. The differences between those and the other intermediate standard versions are small.)

SQL distinguishes between *reserved* and *non-reserved* key words. According to the standard, reserved key words are the only real key words; they are never allowed as identifiers. Non-reserved key words only have a special meaning in particular contexts and can be used as identifiers in other contexts. Most non-reserved key words are actually the names of built-in tables and functions specified by SQL. The concept of non-reserved key words essentially only exists to declare that some predefined meaning is attached to a word in some contexts.

In the Postgres Pro parser, life is a bit more complicated. There are several different classes of tokens ranging from those that can never be used as an identifier to those that have absolutely no special status in the parser, but are considered ordinary identifiers. (The latter is usually the case for functions specified by SQL.) Even reserved key words are not completely reserved in Postgres Pro, but can be used as column labels (for example, `SELECT 55 AS CHECK`, even though `CHECK` is a reserved key word).

In [Table C.1](#) in the column for Postgres Pro we classify as “non-reserved” those key words that are explicitly known to the parser but are allowed as column or table names. Some key words that are otherwise non-reserved cannot be used as function or data type names and are marked accordingly. (Most of these words represent built-in functions or data types with special syntax. The function or type is still available but it cannot be redefined by the user.) Labeled “reserved” are those tokens that are not allowed as column or table names. Some reserved key words are allowable as names for functions or data types; this is also shown in the table. If not so marked, a reserved key word is only allowed as a column label. A blank entry in this column means that the word is treated as an ordinary identifier by PostgreSQL.

Furthermore, while most key words can be used as “bare” column labels without writing `AS` before them (as described in [Section 7.3.2](#)), there are a few that require a leading `AS` to avoid ambiguity. These are marked in the table as “requires `AS`”.

As a general rule, if you get spurious parser errors for commands that use any of the listed key words as an identifier, you should try quoting the identifier to see if the problem goes away.

It is important to understand before studying [Table C.1](#) that the fact that a key word is not reserved in Postgres Pro does not mean that the feature related to the word is not implemented. Conversely, the presence of a key word does not indicate the existence of a feature.

**Table C.1. SQL Key Words**

| Key Word  | PostgreSQL   | SQL:2016     | SQL:2011     | SQL-92       |
|-----------|--------------|--------------|--------------|--------------|
| A         |              | non-reserved | non-reserved |              |
| ABORT     | non-reserved |              |              |              |
| ABS       |              | reserved     | reserved     |              |
| ABSENT    |              | non-reserved | non-reserved |              |
| ABSOLUTE  | non-reserved | non-reserved | non-reserved | reserved     |
| ACCESS    | non-reserved |              |              |              |
| ACCORDING |              | non-reserved | non-reserved |              |
| ACCOUNT   | non-reserved |              |              |              |
| ACOS      |              | reserved     |              |              |
| ACTION    | non-reserved | non-reserved | non-reserved | reserved     |
| ADA       |              | non-reserved | non-reserved | non-reserved |

## SQL Key Words

| Key Word              | PostgreSQL                         | SQL:2016     | SQL:2011     | SQL-92   |
|-----------------------|------------------------------------|--------------|--------------|----------|
| ADD                   | non-reserved                       | non-reserved | non-reserved | reserved |
| ADMIN                 | non-reserved                       | non-reserved | non-reserved |          |
| AFTER                 | non-reserved                       | non-reserved | non-reserved |          |

# Appendix D. SQL Conformance

This section attempts to outline to what extent Postgres Pro conforms to the current SQL standard. The following information is not a full statement of conformance, but it presents the main topics in as much detail as is both reasonable and useful for users.

The formal name of the SQL standard is ISO/IEC 9075 “Database Language SQL”. A revised version of the standard is released from time to time; the most recent update appearing in 2016. The 2016 version is referred to as ISO/IEC 9075:2016, or simply as SQL:2016. The versions prior to that were SQL:2011, SQL:2008, SQL:2006, SQL:2003, SQL:1999, and SQL-92. Each version replaces the previous one, so claims of conformance to earlier versions have no official merit. Postgres Pro development aims for conformance with the latest official version of the standard where such conformance does not contradict traditional features or common sense. Many of the features required by the SQL standard are supported, though sometimes with slightly differing syntax or function. Further moves towards conformance can be expected over time.

SQL-92 defined three feature sets for conformance: Entry, Intermediate, and Full. Most database management systems claiming SQL standard conformance were conforming at only the Entry level, since the entire set of features in the Intermediate and Full levels was either too voluminous or in conflict with legacy behaviors.

Starting with SQL:1999, the SQL standard defines a large set of individual features rather than the ineffectively broad three levels found in SQL-92. A large subset of these features represents the “Core” features, which every conforming SQL implementation must supply. The rest of the features are purely optional.

The standard versions beginning with SQL:2003 are also split into a number of parts. Each is known by a shorthand name. Note that these parts are not consecutively numbered.

- ISO/IEC 9075-1 Framework (SQL/Framework)
- ISO/IEC 9075-2 Foundation (SQL/Foundation)
- ISO/IEC 9075-3 Call Level Interface (SQL/CLI)
- ISO/IEC 9075-4 Persistent Stored Modules (SQL/PSM)
- ISO/IEC 9075-9 Management of External Data (SQL/MED)
- ISO/IEC 9075-10 Object Language Bindings (SQL/OLB)
- ISO/IEC 9075-11 Information and Definition Schemas (SQL/Schemata)
- ISO/IEC 9075-13 Routines and Types using the Java Language (SQL/JRT)
- ISO/IEC 9075-14 XML-related specifications (SQL/XML)
- ISO/IEC 9075-15 Multi-dimensional arrays (SQL/MDA)

The Postgres Pro core covers parts 1, 2, 9, 11, and 14. Part 3 is covered by the ODBC driver, and part 13 is covered by the PL/Java plug-in, but exact conformance is currently not being verified for these components. There are currently no implementations of parts 4, 10, and 15 for Postgres Pro.

Postgres Pro supports most of the major features of SQL:2016. Out of 177 mandatory features required for full Core conformance, Postgres Pro conforms to at least 170. In addition, there is a long list of supported optional features. It might be worth noting that at the time of writing, no current version of any database management system claims full conformance to Core SQL:2016.

In the following two sections, we provide a list of those features that Postgres Pro supports, followed by a list of the features defined in SQL:2016 which are not yet supported in Postgres Pro. Both of these lists are approximate: There might be minor details that are nonconforming for a feature that is listed as supported, and large parts of an unsupported feature might in fact be implemented. The main body of the documentation always contains the most accurate information about what does and does not work.

### Note

Feature codes containing a hyphen are subfeatures. Therefore, if a particular subfeature is not supported, the main feature is listed as unsupported even if some other subfeatures are supported.

## D.1. Supported Features

| Identifier | Core? | Description                                       | Comment                                                     |
|------------|-------|---------------------------------------------------|-------------------------------------------------------------|

## D.2. Unsupported Features

The following features defined in SQL:2016 are not implemented in this release of Postgres Pro. In a few cases, equivalent functionality is available.

| Identifier | Core? | Description    | Comment |
|------------|-------|----------------|---------|
| B011       |       | Embedded Ada   |         |
| B013       |       | Embedded COBOL |         |

| Identifier | Core? | Description                                       | Comment |
|------------|-------|---------------------------------------------------|---------|
| B014       |       | Embedded Fortran                                  |         |
| B015       |       | Embedded MUMPS                                    |         |
| B016       |       | Embedded Pascal                                   |         |

| X281       |       | XMLValidate with DOCUMENT option                        |                                                                  |
| X282       |       | XMLValidate with CONTENT option                         |                                                                  |
| X283       |       | XMLValidate with SEQUENCE option                        |                                                                  |
| X284       |       | XMLValidate: NAMESPACE without ELEMENT clause           |                                                                  |
| X286       |       | XMLValidate: NO NAMESPACE with ELEMENT clause           |                                                                  |
| X300       |       | XMLTable                                                | XPath 1.0 only                                                   |
| X305       |       | XMLTable: initializing an XQuery variable               |                                                                  |

## D.3. XML Limits and Conformance to SQL/XML

Significant revisions to the XML-related specifications in ISO/IEC 9075-14 (SQL/XML) were introduced with SQL:2006. Postgres Pro's implementation of the XML data type and related functions largely follows the earlier 2003 edition, with some borrowing from later editions. In particular:

- Where the current standard provides a family of XML data types to hold “document” or “content” in untyped or XML Schema-typed variants, and a type `XML (SEQUENCE)` to hold arbitrary pieces of XML content, Postgres Pro provides the single `xml` type, which can hold “document” or “content”. There is no equivalent of the standard's “sequence” type.
- Postgres Pro provides two functions introduced in SQL:2006, but in variants that use the XPath 1.0 language, rather than XML Query as specified for them in the standard.

This section presents some of the resulting differences you may encounter.

### D.3.1. Queries Are Restricted to XPath 1.0

The Postgres Pro-specific functions `xpath()` and `xpath_exists()` query XML documents using the XPath language. Postgres Pro also provides XPath-only variants of the standard functions `XML EXISTS` and `XML TABLE`, which officially use the XQuery language. For all of these functions, Postgres Pro relies on the `libxml2` library, which provides only XPath 1.0.

There is a strong connection between the XQuery language and XPath versions 2.0 and later: any expression that is syntactically valid and executes successfully in both produces the same result (with a minor exception for expressions containing numeric character references or predefined entity references, which XQuery replaces with the corresponding character while XPath leaves them alone). But there is no such connection between these languages and XPath 1.0; it was an earlier language and differs in many respects.

There are two categories of limitation to keep in mind: the restriction from XQuery to XPath for the functions specified in the SQL standard, and the restriction of XPath to version 1.0 for both the standard and the Postgres Pro-specific functions.

#### D.3.1.1. Restriction of XQuery to XPath

Features of XQuery beyond those of XPath include:

- XQuery expressions can construct and return new XML nodes, in addition to all possible XPath values. XPath can create and return values of the atomic types (numbers, strings, and so on) but can only return XML nodes that were already present in documents supplied as input to the expression.
- XQuery has control constructs for iteration, sorting, and grouping.
- XQuery allows declaration and use of local functions.

Recent XPath versions begin to offer capabilities overlapping with these (such as functional-style `for-each` and `sort`, anonymous functions, and `parse-xml` to create a node from a string), but such features were not available before XPath 3.0.

#### D.3.1.2. Restriction of XPath to 1.0

For developers familiar with XQuery and XPath 2.0 or later, XPath 1.0 presents a number of differences to contend with:

- The fundamental type of an XQuery/XPath expression, the `sequence`, which can contain XML nodes, atomic values, or both, does not exist in XPath 1.0. A 1.0 expression can only produce a node-set (containing zero or more XML nodes), or a single atomic value.
- Unlike an XQuery/XPath sequence, which can contain any desired items in any desired order, an XPath 1.0 node-set has no guaranteed order and, like any set, does not allow multiple appearances of the same item.

## Note

The libxml2 library does seem to always return node-sets to Postgres Pro with their members in the same relative order they had in the input document. Its documentation does not commit to this behavior, and an XPath 1.0 expression cannot control it.

- While XQuery/XPath provides all of the types defined in XML Schema and many operators and functions over those types, XPath 1.0 has only node-sets and the three atomic types `boolean`, `double`, and `string`.
- XPath 1.0 has no conditional operator. An XQuery/XPath expression such as `if ( hat ) then hat / @size else "no hat"` has no XPath 1.0 equivalent.
- XPath 1.0 has no ordering comparison operator for strings. Both `"cat" < "dog"` and `"cat" > "dog"` are false, because each is a numeric comparison of two NaNs. In contrast, `=` and `!=` do compare the strings as strings.
- XPath 1.0 blurs the distinction between *value comparisons* and *general comparisons* as XQuery/XPath define them. Both `sale/@hatsize = 7` and `sale/@customer = "alice"` are existentially quantified comparisons, true if there is any `sale` with the given value for the attribute, but `sale/@taxable = false()` is a value comparison to the *effective boolean value* of a whole node-set. It is true only if no `sale` has a `taxable` attribute at all.
- In the XQuery/XPath data model, a *document node* can have either document form (i.e., exactly one top-level element, with only comments and processing instructions outside of it) or content form (with those constraints relaxed). Its equivalent in XPath 1.0, the *root node*, can only be in document form. This is part of the reason an `xml` value passed as the context item to any Postgres Pro XPath-based function must be in document form.

The differences highlighted here are not all of them. In XQuery and the 2.0 and later versions of XPath, there is an XPath 1.0 compatibility mode, and the W3C lists of [function library changes](#) and [language changes](#) applied in that mode offer a more complete (but still not exhaustive) account of the differences. The compatibility mode cannot make the later languages exactly equivalent to XPath 1.0.

### D.3.1.3. Mappings between SQL and XML Data Types and Values

In SQL:2006 and later, both directions of conversion between standard SQL data types and the XML Schema types are specified precisely. However, the rules are expressed using the types and semantics of XQuery/XPath, and have no direct application to the different data model of XPath 1.0.

When Postgres Pro maps SQL data values to XML (as in `xmlelement`), or XML to SQL (as in the output columns of `xmltable`), except for a few cases treated specially, Postgres Pro simply assumes that the XML data type's XPath 1.0 string form will be valid as the text-input form of the SQL datatype, and conversely. This rule has the virtue of simplicity while producing, for many data types, results similar to the mappings specified in the standard.

Where interoperability with other systems is a concern, for some data types, it may be necessary to use data type formatting functions (such as those in [Section 9.8](#)) explicitly to produce the standard mappings.

## D.3.2. Incidental Limits of the Implementation

This section concerns limits that are not inherent in the libxml2 library, but apply to the current implementation in Postgres Pro.

### D.3.2.1. Only BY VALUE Passing Mechanism Is Supported

The SQL standard defines two *passing mechanisms* that apply when passing an XML argument from SQL to an XML function or receiving a result: `BY REF`, in which a particular XML value retains its node identity, and `BY VALUE`, in which the content of the XML is passed but node identity is not preserved.

A mechanism can be specified before a list of parameters, as the default mechanism for all of them, or after any parameter, to override the default.

To illustrate the difference, if *x* is an XML value, these two queries in an SQL:2006 environment would produce true and false, respectively:

```
SELECT XMLQUERY('$a is $b' PASSING BY REF x AS a, x AS b NULL ON EMPTY);  
SELECT XMLQUERY('$a is $b' PASSING BY VALUE x AS a, x AS b NULL ON EMPTY);
```

Postgres Pro will accept `BY VALUE` or `BY REF` in an `XML EXISTS` or `XMLTABLE` construct, but it ignores them. The `xml` data type holds a character-string serialized representation, so there is no node identity to preserve, and passing is always effectively `BY VALUE`.

#### **D.3.2.2. Cannot Pass Named Parameters to Queries**

The XPath-based functions support passing one parameter to serve as the XPath expression's context item, but do not support passing additional values to be available to the expression as named parameters.

#### **D.3.2.3. No XML (SEQUENCE) Type**

The Postgres Pro `xml` data type can only hold a value in `DOCUMENT` or `CONTENT` form. An XQuery/XPath expression context item must be a single XML node or atomic value, but XPath 1.0 further restricts it to be only an XML node, and has no node type allowing `CONTENT`. The upshot is that a well-formed `DOCUMENT` is the only form of XML value that Postgres Pro can supply as an XPath context item.

---

# Appendix E. Release Notes

The release notes contain the significant changes in each Postgres Pro Enterprise release, with major features and migration issues listed at the top. The release notes do not contain changes that affect only a few users or changes that are internal and therefore not user-visible. For example, the optimizer is improved in almost every release, but the improvements are usually observed by users as simply faster queries.

## E.1. Postgres Pro Enterprise 14.20.1

**Release Date:** 2025-12-16

### E.1.1. Overview

This release is based on PostgreSQL 14.20 and Postgres Pro Enterprise 14.19.1. All changes inherited from PostgreSQL 14.20 are listed in [PostgreSQL 14.20 Release Notes](#). As compared with Postgres Pro Enterprise 14.19.1, this version also provides the following changes:

- Improved the search mechanism for matching `mchar` and `varchar` strings using the `LIKE` operator. Optimized case-insensitive comparison results in significant speed increase. This may be useful for 1C.
- Improved performance of [getting information on crashes of a backend](#) by optimizing utility functions and commands.
- Improved performance in cases where [resource prioritization](#) is disabled.
- Added the [enable\\_sorted\\_merge\\_join](#) configuration parameter that enables or disables the query planner's use of merge joins in plans with sorting.
- Added the [max\\_wal\\_segments\\_prealloc](#) configuration parameter, which enables the background writer to create WAL segments in advance during its main operation cycle, reducing the load on backend processes. The parameter sets the maximum number of such segments.
- Limited the maximum number of assigned transaction IDs to  $2^{63}$ . Now a warning is also shown when a threshold of 10 million XIDs is reached. Once the maximum number of XIDs is reached, new transactions cannot be started, but read-only queries continue to work.
- Avoided a possible pfree-a-NULL-pointer crash after an error in OpenSSL connection setup.
- Fixed an issue with [CFS](#) failing to compress relation files where OID exceeds `INT32_MAX`. The issue occurred when moving an existing table to a CFS tablespace.
- Added new values of the `PGPRO_TUNE` environment variable used by [initdb](#).
- Added the [auto\\_dump](#) extension, which collects data for long-running and problematic queries and creates files with all information to reproduce them for troubleshooting.
- Added the [pg\\_trgm\\_mchar](#) extension, which allows fast trigram-based search for similar `mchar` and `varchar` strings. This extension also provides support of GIN indexes for `mchar` and `varchar` types. This may be useful for 1C.
- Added the [pgpro\\_cpumeter](#) extension, which provides access to a new CPU usage monitoring system function. This `pgpro_cpumeter` function continuously collects and records information about CPU cores used by Postgres Pro server processes.
- Upgraded [multimaster](#) to provide the following changes and bug fixes:
  - Fixed an issue where multimaster returned an error when executing read-write transactions containing queries to [postgres\\_fdw](#) foreign tables. The root cause was that `postgres_fdw` does not support two-phase commit transactions used by multimaster. To fix the issue, the [postgres\\_fdw.read\\_only\\_transactions](#) configuration parameter was implemented. When set to `on`, it enables read-only queries to foreign tables in read-write transactions, which allows seamless operation of multimaster and `postgres_fdw`.

- Fixed an issue of potential transaction commit latency caused by an error in the exchange logic for messages containing information about transaction application on nodes.
- Upgraded orafce to version 4.16.3.
- Upgraded [pageinspect](#) to fix an issue with the `page_header` function, which returned incorrect information for `double xmax` and some index pages. Specifically, the sequence of columns was confused and the `prune_xid` value was returned in the `xid_base` column. Now the information is returned correctly.
- Upgraded [pg\\_filedump](#) to version 18.0.
- Upgraded [pg\\_hint\\_plan](#) to version 1.4.4.
- Upgraded `pg_portal_modify` to version 0.3.6.
- Upgraded [pg\\_proaudit](#) to provide the following enhancements and bug fixes:
  - Added support for logging of the following event types: `ANALYZE`, `DISCARD ALL`, `DISCARD PLANS`, `DISCARD SEQUENCES`, `DISCARD TEMP` (for temporary tables), `CHECKPOINT`, `FETCH`, and `MOVE`.
  - Added the new event class `MISC`. This class allows logging of all events (including those mentioned above) not related to other event classes.
  - Added a [new method](#) for logging security events. Events in CEF format can now be logged not only in a separate file but also in syslog.
  - Added a new event log field: application name. `AUTHENTICATE` events now contain the name of the initiating application alongside the connection parameters.
  - Fixed an issue with `pg_proaudit` failing to log security events in a CEF file.
  - Fixed an issue with `pg_proaudit` failing to log events for the `INSERT` command following `CREATE` within anonymous code blocks (the `DO` command) and stored procedures/functions.
  - Fixed an issue with `pg_proaudit` overloading a CPU core due to failed log rotation.
- Upgraded [pg\\_probackup](#) to version 2.8.11 Enterprise, which provides the following new features, optimizations, and bug fixes:
  - Added support for Postgres Pro Enterprise 18.
  - Added support for Transparent Data Encryption (TDE). The version output of `pg_probackup` now displays a TDE support indicator.
  - Made the host from which a backup was taken to be saved in `backup.control` and displayed in the `show` command output.
  - Improved the behavior during restore from read-only media, including more informative warning messages.
  - For `archive-push` and `archive-get` operations in the remote mode, made `SIGQUIT` signals to be ignored to prevent core dumps of helper programs when the server stops.
  - Added validation to ensure consistency between the port number in `PGDATA` and the `--pgport` option. Also added the `--force` flag to perform backups even when these values mismatch.
  - Fixed handling of external tablespaces during incremental restore. When using the `--force` flag, the tablespace contents are no longer overwritten.
  - Fixed a problem with the `backup` command holding the replication slot after successful completion.
  - Fixed the identifier conflict for the `--wal-tree` option by adding a uniqueness test.
  - Fixed the order of displaying the calculated and expected checksum values in the warning message.
- Upgraded [pg\\_repack](#) to version 1.5.3.

- Upgraded [pgpro\\_bindump](#) to fix compression level validation. Previously, `pgpro_bindump` enforced the same compression-level range regardless of the selected algorithm.
- Upgraded [pgpro\\_controldata](#) to version 18.1.0.
- Upgraded [pgpro\\_datactl](#) to version 1.2.
- Upgraded [pgpro\\_pwr](#) to version 4.12, which provides optimizations and bug fixes. Notable changes are as follows:
  - Improved `take_sample` time tracking.
  - Added support of [pgpro\\_stats](#) 1.10.
  - Added a possibility to exclude server connection strings from dumps.
  - Added statistics on restartpoints to the reports when it is available.
- Upgraded [pgpro\\_scheduler](#) to fix an issue with incorrectly recording timestamp values in the service table associated with the `get_log` function. Now missing data is properly recorded when a NULL value is specified.
- Upgraded [pgpro\\_stats](#) to version 1.10 to provide the following enhancements and bug fixes:
  - Added new statistics to `pgpro_stats_statements` and `pgpro_stats_totals` views. These statistics were added to `pg_stats_statements` in Postgres Pro 18. Related functions are updated accordingly.
  - Added the new `pgpro_stats_statements_filtered` function to filter statistics similar to those provided in the `pgpro_stats_statements` view by one or several fields: `userid`, `dbid`, `queryid`, and `planid`. Calling this function is faster than querying the `pgpro_stats_statements` view with appropriate values of these fields.
  - Improved the behavior of [pgpro\\_stats](#) similarly to [pg\\_stat\\_statements](#). The changes are:
    - Allow the parameterization of [SET](#) values. This reduces the bloat caused by `SET` statements with differing constants.
    - Allow the parameterization of constant lists.
  - Fixed an issue that could occur when in `pgpro_stats` custom metrics were changed on the fly. Now any change to custom metrics requires a server restart.
- Upgraded `pldebugger` to version 1.1.6.
- Upgraded [rum](#) to fix a bug with the module upgrade that was caused by an incorrect variable specified in its makefile.
- Upgraded `tds_fdw` to version 2.0.5.
- Disabled [online\\_analyze](#). This module is not recommended for use with modern versions of 1C. However, it can be enabled if needed.

### E.1.2. Migration to Version 14.20.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

ABI versions may change between minor releases of Postgres Pro. If this is the case, and you see the `ABI mismatch` error when trying to run your extension, make sure to install a new version of the extension supplied with a new release of Postgres Pro, or recompile your third-party extension to be able to use it with the current version of Postgres Pro.

When upgrading your high-availability cluster from Postgres Pro Enterprise versions 14.12.x or lower, first disable automatic failover if it was enabled and upgrade all the standby servers, then upgrade the primary server, promote a standby, and restart the former primary (possibly with `pg_rewrite`).

If you take backups using `pg_probackup` and you have previously upgraded it to version 2.8.0 Enterprise or 2.8.1 Enterprise, make sure to upgrade it to version 2.8.2 Enterprise or higher and retake a full backup

after upgrade, since backups taken using those versions might be corrupted. If you suspect that your backups taken with versions 2.8.0 or 2.8.1 may be corrupted, you can validate them using version 2.8.2.

If you are migrating to the current major version of Postgres Pro Enterprise using [pg\\_upgrade](#), and you want to keep the existing visibility map representation in [pageinspect](#), you should run the `VACUUM` command before the upgrade.

Starting from Postgres Pro Enterprise 14.10.1, the privileges of `CREATEROLE` are restricted, and modification of other roles requires the role requesting the change to have the `ADMIN OPTION` permission.

It is strongly recommended to avoid migrating a cluster with 32-bit transaction IDs to Postgres Pro Enterprise versions below 14.9.2, if there are multitransactions in your database, as it may cause data corruption.

When upgrading to Postgres Pro Enterprise versions starting with 14.8.1, make sure to upgrade [pg\\_probackup](#) Enterprise to version 2.6.4 or higher since lower versions are incompatible with these Postgres Pro Enterprise versions.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.2. Postgres Pro Enterprise 14.19.1

**Release Date:** 2025-09-24

### E.2.1. Overview

This release is based on PostgreSQL 14.19 and Postgres Pro Enterprise 14.18.1. All changes inherited from PostgreSQL 14.19 are listed in [PostgreSQL 14.19 Release Notes](#). As compared with Postgres Pro Enterprise 14.18.1, this version also provides the following changes:

- Improved performance by suppressing catalog cache invalidation messages for DDL operations on temporary tables and for analyzing these tables. This is useful for 1C.
- Improved performance by avoiding invalidation of the `pg_internal.init` file when analyzing catalog tables, particularly when statistics for these tables change frequently. This may be useful for 1C.
- Improved performance by reducing the number of lock requests for the [pg\\_attribute](#) and [pg\\_statistic](#) tables for queries with a large number of relations that are not present in the system cache. This may be useful for some usage scenarios with 1C.
- Improved performance of non-transactional truncate operations on temporary tables and [fast truncate](#) operations. This is useful for 1C.
- Optimized the behavior when working with the [COALESCE](#) function. Now this function is replaced with one of its arguments if all other arguments were evaluated to `null`. This allows improving the selectivity of query clauses and producing better execution plans.
- Introduced the following changes to the implementation of [crash\\_info](#):
  - Added the [crash\\_info\\_timer](#), [crash\\_info\\_timer\\_interval](#), and [crash\\_info\\_query\\_threshold](#) configuration parameters that allow profiling long queries in `crash_info` output files.
  - Extended the diagnostic information that the [crash\\_info\\_dump](#) configuration parameter can specify to write in case of a backend crash. By default, now the general information on the signal is dumped and for Linux x64, also the information on the processor state and bytes near RIP (return instruction pointer). All this ensures better diagnostics, in particular, in case of `SIGILL` (illegal instruction) signals. The way of dumping stack files in case of crashes has also been changed for Linux x64. Besides, `memory_context` has been removed from the default list of sources to be dumped in order to avoid failures that could occur when writing the diagnostic information.

- Implemented the following enhancements and bug fixes for [CFS](#):
  - Improved compressed tablespace operations on s390/s390x architectures.
  - Improved the compression ratio estimation for tables using the `cfs_estimate(relation)` function. Note that `cfs_estimate(relation)` should be used only *after a checkpoint* to avoid incorrect estimations.
  - Disabled truncation for compressed relations during vacuum operations.
  - Removed encryption support for CFS, including the `cfs_encryption` configuration parameter.
- Fixed excessive memory usage by the disabled built-in [connection pool](#).
- Fixed an issue with [autonomous transactions](#), which caused a failure to release resources, leading to accumulation of cached plan references.
- Fixed page image inconsistency during heap insert on an empty page. Previously, this could result in incorrect page contents on standby servers.
- Fixed an issue with page conversion from 32-bit to 64-bit format after migration to Postgres Pro Enterprise using `pg_upgrade`. When a page was converted only in memory, without writing it to disk, and autovacuum removed corresponding `pg_xact` segments at the same time, transaction status in tuples was lost, leading to errors on access.
- Fixed a possible race condition in the `walreceiver` process.
- Fixed an issue in `LISTEN/NOTIFY` queue handling, which caused failure to obtain transaction status. Previously, `VACUUM FREEZE` could advance `datfrozenxid` too far forward.
- Fixed an issue where the planner could choose non-optimal execution plans for queries that use the `LIKE` operator with the `mchar` data type.
- Added support for Debian 13, Red Hat Enterprise Linux 10, Rocky Linux 10, Oracle Linux 10, and AlmaLinux 10.
- Ended support for Ubuntu 20.04.
- Upgraded [aqo](#) to provide the following bugfixes:
  - Fixed the race condition when calling the `aqo_cleanup` function from different sessions.
  - Fixed an issue where `aqo` learning data was not saved for queries that use materialization.
- Upgraded [auto\\_explain](#) to move the planning time of a query in the output to a separate line under the planner tree, as in the `EXPLAIN` output. With the former location of the planning time in the output, [pgbadger](#) could not recognize the information on a query and therefore did not include it in the report.
- Fixed an issue where [fasttrun](#) could fail to fully truncate temporary tables if the cached segment count was smaller than the actual number of file segments on disk, leaving disk space occupied even though the table appeared empty.
- Upgraded [multimaster](#) to provide the following enhancements and bug fixes:
  - Improved the ability of the node to return to normal operation after catchup by accelerating the transaction filter building process at the start of `walreceiver`.
  - Fixed a bug that caused recovery hanging and potential data desynchronization when adding a new node.
  - Fixed unexpected errors in execution of DDL commands that were caused by incorrect processing of catalog cache invalidation messages.
- Implemented the ability to configure LDAP authentication for [pgbouncer](#) by means of [PAM](#) (Pluggable Authentication Modules). For more information, see [LDAP Authentication Configuration for pgbouncer](#).

- Updated the [pg\\_freespacemap](#) module to include the `pg_freespace_relation_logical_blocks` function for computing the disk space used by relation forks. This function works with both compressed and uncompressed tables.
- Fixed a memory allocation issue in [pg\\_prewarm](#), which could previously produce errors like “invalid memory alloc request size” when [shared\\_buffers](#) was set to a huge value.
- Upgraded [pg\\_proaudit](#) to provide the following enhancements:
  - Added support for CEF format for event log files.
  - Adjusted `pg_proaudit` output. `xid` and `vxid` fields are no longer displayed if they are zero.
- Upgraded [pg\\_probackup](#) to version 2.8.10 Enterprise, which provides the following new features, optimizations, and bug fixes:
  - Added the `--wal-tree` option for the `add-instance` command to store archived WAL files in a tree-like structure. This improves WAL operation performance with large volumes of logs.
  - Added the `postgres-edition` field to the `show` command output in the JSON format to display DBMS edition information.
  - Improved the `--dry-run` option operation during tablespace recovery. The operation estimation and plan output are now more precise.
  - Fixed an issue related to the retention window calculation. The time value is now taken from the host where `pg_probackup` is running. The retention window is now calculated correctly even with the timezone differences between the servers.
  - Fixed a problem with the `archive-get` command operation. The `pbk_prefetch` directory is now created with correct access rights, inheriting permissions from PGDATA.
  - Fixed false failure of the `checkdb` command in the remote mode during concurrent TRUNCATE operations or table drops on standby nodes.
- Fixed the following issues in the [pgpro\\_bindump](#) module:
  - Fixed potential [pg\\_probackup3](#) failure caused by temporary tables during backup validation using the `pgpro_bindump` module in the PRO mode.
  - Fixed a memory leak in [pg\\_probackup3](#) using the `pgpro_bindump` module for PTRACK operations.
  - Fixed an issue that could cause infinite looping in [pg\\_probackup3](#) when using the `pgpro_bindump` module.
  - Fixed an issue with multi-timeline backup in the PTRACK mode in [pg\\_probackup3](#) using the `pgpro_bindump` module in the PRO mode.
- Updated the [pgpro\\_datactl](#) utility to include the following new features:
  - Added the `repack` command for changing the compression algorithm and/or compression level of CFS files.
  - Added the `ground` command for replacing corrupted blocks with zeros to prevent potential operation failures.
  - Added the `stat` command to monitor tablespace statistics.
- Upgraded [pgpro\\_pwr](#) to version 4.10, which completely redesigns the report and supports PostgreSQL 18.
- Upgraded [pgpro\\_scheduler](#) to version 2.12, which provides the following bug fixes and improvements:
  - Added two `schedule.clean_at_jobs_done` [cleanup functions](#) with the same name but different argument types. These functions delete records from the `schedule.at_jobs_done` table that are older either than a specified interval or a specified timestamp.

- Provided the ability to change the next start time for a cron job that has `next_time_statement` by updating `cron`, `date`, `dates`, or `rule` using the `set_job_attributes()` function.
- Upgraded [pgpro\\_stats](#) to fix a segmentation fault that could occur when defining custom metrics. The error originated from a memory allocation issue, which was fixed.
- Fixed an issue with incorrect configuration parameter values specified when using the `1c.tune` preset of the [pgpro\\_tune](#) utility.
- Upgraded [pg\\_query\\_state](#) to version 1.2 to add the [pg\\_progress\\_bar](#) and [pg\\_progress\\_bar\\_visual](#) functions that allow monitoring the current progress of query execution.
- Added the `--enable-large-mem-buffers` option to the [pg\\_restore](#) to allow restoring a database that does not contain large `bytea` values and records with several `text` values as a non-superuser.
- Fixed an issue in [postgres\\_fdw](#), which could cause `UPDATE` and `DELETE` queries with a `RETURNING` clause to fail with “out of memory for query result” errors. Now `RETURNING` results are processed row-by-row.
- Upgraded [rum](#) to provide the following bugfixes:
  - Fixed a segmentation fault caused by invalid memory access when a buffer pointer was used after the underlying buffer was modified by another thread.
  - Fixed an index scan infinite loop when using multiple `ORDER BY` clauses.

## E.2.2. Migration to Version 14.19.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

ABI versions may change between minor releases of Postgres Pro. If this is the case, and you see the `ABI mismatch` error when trying to run your extension, make sure to install a new version of the extension supplied with a new release of Postgres Pro, or recompile your third-party extension to be able to use it with the current version of Postgres Pro.

When upgrading your high-availability cluster from Postgres Pro Enterprise versions 14.12.x or lower, first disable automatic failover if it was enabled and upgrade all the standby servers, then upgrade the primary server, promote a standby, and restart the former primary (possibly with `pg_rewind`).

If you take backups using `pg_probackup` and you have previously upgraded it to version 2.8.0 Enterprise or 2.8.1 Enterprise, make sure to upgrade it to version 2.8.2 Enterprise or higher and retake a full backup after upgrade, since backups taken using those versions might be corrupted. If you suspect that your backups taken with versions 2.8.0 or 2.8.1 may be corrupted, you can validate them using version 2.8.2.

If you are migrating to the current major version of Postgres Pro Enterprise using [pg\\_upgrade](#), and you want to keep the existing visibility map representation in [pageinspect](#), you should run the `VACUUM` command before the upgrade.

Starting from Postgres Pro Enterprise 14.10.1, the privileges of `CREATEROLE` are restricted, and modification of other roles requires the role requesting the change to have the `ADMIN OPTION` permission.

It is strongly recommended to avoid migrating a cluster with 32-bit transaction IDs to Postgres Pro Enterprise versions below 14.9.2, if there are multitransactions in your database, as it may cause data corruption.

When upgrading to Postgres Pro Enterprise versions starting with 14.8.1, make sure to upgrade [pg\\_probackup](#) Enterprise to version 2.6.4 or higher since lower versions are incompatible with these Postgres Pro Enterprise versions.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.3. Postgres Pro Enterprise 14.18.1

**Release Date:** 2025-06-03

### E.3.1. Overview

This release is based on PostgreSQL 14.18 and Postgres Pro Enterprise 14.17.1. All changes inherited from PostgreSQL 14.18 are listed in [PostgreSQL 14.18 Release Notes](#). As compared with Postgres Pro Enterprise 14.17.1, this version also provides the following changes:

- Added the [enable\\_alternative\\_sorting\\_cost\\_model](#) configuration parameter, which allows you to enable or disable the query planner's use of alternative model for estimating the cost of tuple sorting.
- Implemented performance optimization when working with table metadata, which allows obtaining information about attributes using the system cache instead of direct reading from the system catalog.
- Introduced the following changes to the implementation of [crash\\_info](#):
  - Added handling of SIGILL signals to `crash_info` processing.
  - Added details, like process start time and query text at planning, to `crash_info` output files.
  - Fixed incorrect function names in the first 2-3 lines of `crash_info` backtrace stacks.
  - Fixed possible data truncation at the end of SQL query dump files. Previously, a buffer overflow during SQL query dumping could result in incomplete writes, causing truncated data at the end of files produced by `crash_info`.
  - Fixed handling of crash information signals (sent using the kill command) by backends. Previously, the first signal would flush `crash_info` information to the log, but the process would continue running without producing a core dump, even if configured, and only the second signal would terminate the backend and generate the core dump as expected.
- Fixed the following issues for [CFS](#):
  - Fixed compatibility of CFS with the `ALTER TABLESPACE ... SET/RESET` commands.
  - Fixed an issue with memory allocation within a critical section in the implementation of `VACUUM ANALYZE` for compressed tables.
- Fixed the following bugs related to [autonomous transactions](#):
  - Fixed a segmentation fault, which could occur when using [postgres\\_fdw](#) with autonomous transactions.
  - Fixed loss of temporary tables from parent transaction on autonomous transaction rollback.
  - Fixed an issue with empty `xact_start` columns in the `pg_stat_activity` view for backends executing autonomous transactions.
- Fixed an issue with missing statistics about vacuuming when multiple index vacuum workers are used.
- Fixed an issue when the checkpointer process could get stuck, repeatedly throwing “invalid memory alloc request size” errors. This could occur when using a huge `shared_buffers` setting, causing checkpointer memory allocation requests to exceed the allowed limit.
- Fixed misuse of spinlocks in the automatic page repair worker.
- Added the [daterange\\_inclusive](#) extension, which allows you to include the upper bound of a time range in output.
- Added the [pg\\_failover\\_slots](#) extension as a separate pre-built package. `pg_failover_slots` is designed for automatic creation and synchronization of logical replication slots on physical replicas.
- Added the [pg\\_probackup3](#) solution for backup and recovery of Postgres Pro database clusters. Refer to the [pg\\_probackup3 release notes](#) for more details.

- Added the [pgpro\\_bindump](#) module to manage backup and restore operations. This module implements specialized replication commands for an extended replication protocol, has its own format for archiving files, and does not require SSH connection. It is designed specifically for use with the [pg\\_probackup3](#) utility.
- Added the [pgpro\\_datactl](#) utility to manage Postgres Pro data files, which includes a module for unpacking and analyzing CFS files.
- Added the new [pgpro\\_tune](#) utility for automatic tuning of Postgres Pro configuration parameters for all operating systems, except for Windows.
- Added a new `PGPRO_TUNE` environment variable to [initdb](#), which specifies whether to use [pgpro\\_tune](#) without modifying command-line options directly.
- Deprecated the experimental vops extension.
- Removed the `--tune` option from `pg-setup`. Use the new [pgpro\\_tune](#) utility instead.
- Upgraded [multimaster](#) to version 1.3.0, which provides the following enhancements and bug fixes:
  - Improved the way nodes delete old synchronization points. Previously, every node deleted only a part of the synchronization point table and replicated changes to other nodes. This could cause synchronization issues and inability to delete old synchronization points. Now, every node deletes all synchronization points and does not replicate changes to other nodes.
  - Fixed potential node hanging during catchup when attempting to process aborted DDL transactions in a cluster of three or more nodes.
- Upgraded [oracle\\_fdw](#) to provide the following enhancements and bug fixes:
  - Increased line size for EXPLAIN output as some Oracle catalog queries have long filter conditions. The line size was increased to the value of 3000.
  - Fixed a crash with column options on non-existing columns. If the Oracle table has fewer columns than the Postgres Pro and one of these extra columns has a column option set, `oracle_fdw` would write past the end of an array, leading to memory corruption and crashes. Now options for such columns are ignored.
- Fixed an issue with updating [pageinspect](#). In rare cases, depending on the sequence of previous updates, upgrading the database cluster and then attempting to update the `pageinspect` extension using `ALTER EXTENSION pageinspect UPDATE TO` could result in an error. To avoid such issues, it is strongly recommended to drop and recreate the extension using `DROP EXTENSION` followed by `CREATE EXTENSION` after upgrading the cluster. Since `pageinspect` does not create dependent objects, this approach is safe.
- Upgraded [pg\\_proaudit](#) to provide the following enhancements and bug fixes:
  - Added new object types: `CATALOG RELATION` and `CATALOG FUNCTION`.
  - Added new event fields: `UUID`, `XID`, and `VXID`. Now it is possible to identify an event by its `UUID` and transaction IDs (if applicable).
  - The behavior of the `pg_proaudit.log_catalog_access` configuration parameter was corrected to reflect the new logic of logging for system catalog objects.
  - Changed the logic of handling disconnection events. Now these events are associated with the corresponding authentication events, so the disconnection events will be logged even in the case when the rule is removed after authentication, but before disconnect.
  - Fixed an issue where the `DISCONNECT` event type was not logged for a user who was a member of the role that was set in the logging rule.
  - Fixed the bug that caused a log entry to be written to an incorrect log file when log file rotation was configured.
  - Fixed an issue with `pg_proaudit` failing to log schema creation events.

- Corrected the behavior of the `logger` process when deleting a role from a parallel session configured by the rule.
- Upgraded [pg\\_probackup](#) to version 2.8.9 Enterprise, which provides the following new features, optimizations, and bug fixes:
  - Added the `maintain` command to resolve issues that can occur during a forced backup termination.
  - Added the `--lock-lifetime` option that sets the timeout for locks. This option is useful for computational environments with a slow network.
  - Stabilized retaining the initial permissions for directories when running the `init` command.
  - Stabilized the `checkdb` command on a remote host.
  - Improved the stability of the point-in-time recovery (PITR) with validation.
  - Fixed the “SignatureDoesNotMatch” error that could occur when connecting to the VK Cloud S3 storage.
  - Fixed an incorrect behavior that could occur when launching the wait for a WAL streaming thread in the ARCHIVE WAL delivery mode.
- Upgraded [pgpro\\_pwr](#) to version 4.9, which mainly provides optimizations and bug fixes. Notable changes are as follows:
  - Added support for [pgpro\\_stats](#) 1.9.
  - Added a possibility to define the mode of collecting relation sizes globally through the `pgpro_pwr.relsizes_collect_mode` extension parameter or for a server through the `set_server_size_sampling` function parameter.
  - Enabled fine-tuning the server statistics collection by calling the `set_server_setting` function. It allows you to define which statistics should be collected.
  - Added a preview of storage parameters for tables and indexes in the “Schema object statistics” report section.
- Upgraded [pgpro\\_scheduler](#) to version 2.11.2 to fix an issue where repeated jobs could be executed at additional time if days of the week were set using the `crontab` format. `pgpro_scheduler` now checks all job time settings and runs jobs at the specified time.
- Upgraded [pgpro\\_stats](#) to version 1.9, which provides the following bug fixes and improvements:
  - Enhanced session tracing to provide more information. Specifically, the new `time_info` filter attribute controls inclusion of additional information in the session-tracing output, and the `pgpro_stats.trace_query_text_size` configuration parameter can limit the size of the query in the session-tracing output.
  - Aligned the names of the `explain_*` filter attributes of the session tracer with the names of session-tracing configuration parameters.
  - Changed the format of the statistics dump file and the corresponding save/load routines.
  - Implemented turning off the session tracer functionality when no session-tracing filters are specified.
  - Prohibited inclusion of both [pgpro\\_stats](#) and [pg\\_stat\\_statements](#) in the list of `shared_preload_libraries`. If both are included, the database server will not start.
- Upgraded the [pg\\_wait\\_sampling](#) extension to provide the following bug fixes:
  - Fixed an issue where GUC variables could be overridden when using parallel workers.
  - Fixed an issue with malformed samples caused by a race condition when `pg_wait_sampling.sample_cpu` is disabled.

### E.3.2. Migration to Version 14.18.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

ABI versions may change between minor releases of Postgres Pro. If this is the case, and you see the `ABI mismatch` error when trying to run your extension, make sure to install a new version of the extension supplied with a new release of Postgres Pro, or recompile your third-party extension to be able to use it with the current version of Postgres Pro.

When upgrading your high-availability cluster from Postgres Pro Enterprise versions 14.12.x or lower, first disable automatic failover if it was enabled and upgrade all the standby servers, then upgrade the primary server, promote a standby, and restart the former primary (possibly with `pg_rewind`).

If you take backups using `pg_probackup` and you have previously upgraded it to version 2.8.0 Enterprise or 2.8.1 Enterprise, make sure to upgrade it to version 2.8.2 Enterprise or higher and retake a full backup after upgrade, since backups taken using those versions might be corrupted. If you suspect that your backups taken with versions 2.8.0 or 2.8.1 may be corrupted, you can validate them using version 2.8.2.

If you are migrating to the current major version of Postgres Pro Enterprise using [pg\\_upgrade](#), and you want to keep the existing visibility map representation in [pageinspect](#), you should run the `VACUUM` command before the upgrade.

Starting from Postgres Pro Enterprise 14.10.1, the privileges of `CREATEROLE` are restricted, and modification of other roles requires the role requesting the change to have the `ADMIN OPTION` permission.

It is strongly recommended to avoid migrating a cluster with 32-bit transaction IDs to Postgres Pro Enterprise versions below 14.9.2, if there are multitransactions in your database, as it may cause data corruption.

When upgrading to Postgres Pro Enterprise versions starting with 14.8.1, make sure to upgrade [pg\\_probackup](#) Enterprise to version 2.6.4 or higher since lower versions are incompatible with these Postgres Pro Enterprise versions.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.4. Postgres Pro Enterprise 14.17.1

**Release Date:** 2025-03-05

### E.4.1. Overview

This release is based on PostgreSQL 14.17 and Postgres Pro Enterprise 14.15.1. All changes inherited from PostgreSQL 14.17 are listed in [PostgreSQL 14.17 Release Notes](#). As compared with Postgres Pro Enterprise 14.15.1, this version also provides the following changes:

- Added details, like current working directory, the `PGDATA` directory, etc., to `crash_info` output files.
- Added the increased security requirements for the [CREATE PROFILE](#) command. Now the `PASS-WORD_REQUIRE_COMPLEX` parameter requires characters from three different groups. Also, all characters of languages without case distinction (Hindi, Chinese, etc.) in the UTF-8 encoding are considered lowercase.
- Implemented the following enhancements and bug fixes for [CFS](#):
  - Changed the default value for the [cfs\\_gc\\_threshold](#) configuration parameter from 50 to 30 percent.
  - Fixed an issue with CFS garbage collector being blocked by the backup process. If backup took ran too long, this could lead to write locks, preventing writes to compressed tablespaces. Now both processes lock only specific data files briefly, avoiding mutual blocking.

- Fixed an issue with missing compression settings for tablespaces on standby servers by adding a new WAL record type. Previously, standby servers did not receive such compression settings because `ALTER TABLESPACE ... SET (compression=true)` was not logged in WAL.
- Fixed the `cfs_start_gc` function to reject invalid values of the `n_workers` argument.
- Fixed an issue with upgrading Postgres Pro Standard to Postgres Pro Enterprise using `pg_upgrade`, which could fail if the old cluster had an epoch greater than 1 with an error like “could not open file”.
- Fixed the `pg_upgrade --check` option to correctly check that `pg_upgrade` is run on a standby. Previously, it would fail with errors like “cannot assign TransactionIds during recovery”.
- Fixed a segmentation fault caused by foreign data wrapper invalidation during `autonomous transactions` if an autonomous transaction reset global variables while registered callback functions remained active. Now callback functions check for global variables and invalidation data is preserved for parent transactions.
- Fixed an issue that caused the server to crash with PANIC instead of returning an appropriate error when deleting tuples from a page where the difference between the minimum transaction ID and the current transaction ID exceeded  $2^{31}$ .
- Fixed `pg_multixact` bloating by introducing “soft” limits that trigger `autovacuum` earlier.
- Fixed an issue where `crash_info` could fail to write diagnostic files when handling a stack overflow. Previously, the signal handler ran on the same stack that had overflowed, which could prevent it from executing due to lack of available stack space. Now the handler runs on an alternate signal stack.
- Fixed a memory context issue, which could previously cause emitting garbage in logs instead of the host and port details when disconnecting from the remote server.
- Fixed an issue that could occur when a custom scan was used, which could cause an incorrect state of the query plan and could result in an error when `pgpro_stats` was involved.
- Fixed an issue where roles without explicitly set `VALID UNTIL` attribute and associated with a profile that had `PASSWORD_GRACE_TIME` set to 0 and `PASSWORD_LIFE_TIME` set to `UNLIMITED` incorrectly received password expiration warnings. Now they are correctly considered valid indefinitely.
- Upgraded the `apache_age` extension to version 1.5.1.
- Optimized `fasttrun` to skip unnecessary truncate operations on empty temporary relations.
- Upgraded `mamonsu` to version 3.5.11 to provide support for `pgpro_stats` version 1.8.
- Upgraded `multimaster` to add the ability to specify the catchup mode for reconnected nodes using the `multimaster.catchup_algorithm` configuration parameter. Supported the `parallel` catchup mode, in which non-conflicting replicated transactions are applied in parallel.
- Upgraded `pgbadger` to version 13.0.
- Upgraded `pgbouncer` to version 1.24.0.
- Upgraded `pg_hint_plan` to version 1.4.3.2.
- Upgraded `pg_portal_modify` to version 0.3.5.
- Upgraded `pg_proaudit` to provide the following enhancements and bug fixes:
  - Added a new event field: session user name. Now an event contains the information about both `session_user` and `current_user` attributes of an SQL session.
  - Added support for new event classes: `ALL_DDL_NONTEMP` and `ALL_DML_NONTEMP`. The scope of these classes is limited to the objects that are not contained in `pg_temp_nnn` temporary schemas.
  - Fixed logging of `SELECT FOR UPDATE` and `SELECT FOR KEY SHARE` events as `SELECT`, rather than `UPDATE`.
- Upgraded `pg_probackup` to version 2.8.7 Enterprise, which provides the following optimizations and bug fixes:
  - Reduced the log level for “checking WAL file name” messages that are issued when the `show` with the `--archive` option is executed from `INFO` to `VERBOSE`.

- Updated the `add-instance` command logic to make the `-D` option that specifies the path to the catalog mandatory. `add-instance` no longer relies on the `PGDATA` environment variable for the catalog location, but requires explicitly specifying the path to the catalog as the command option.
- Improved the garbage collection mechanism in CFS used when a backup copy is created. File-system level locks resolve an issue with the concurrent access to files from compressed tablespaces during copying to a backup and during the defragmentation.
- Fixed an issue of the multi-threaded file copying technique that prevents repeated copying of one file. This issue could previously stop the backup creation under high load on the server.
- Upgraded `pgpro_pwr` to version 4.8, which provides new features and bug fixes. Notable changes are as follows:
  - Added tracking of extension versions installed in the cluster through a new report section.
  - Added a possibility to hide data for certain databases in the report. To this end, a new parameter that accepts an array of databases to be excluded was added to report generation functions.
- Upgraded `pgpro_scheduler` to version 2.11.1 to fix a segmentation fault, which could occur when `pgpro_scheduler` did not terminate its processes when the associated extension or schema was dropped. Now it terminates with an error instead of crashing.
- Upgraded `pgpro_stats` to version 1.8.1, which provides the following bug fixes and improvements:
  - Fixed an issue that could occur during session tracing and cause errors “could not write file `pg_stat/pgpro_stats_filters.trace.tmp`”: No such file or directory”. Concurrent writing from different sessions to a trace file is fixed now, so processes can write to the trace file in parallel without collisions.
  - Implemented an optimization that lowers the locking time in some cases when copying metrics from the local memory to the shared memory.
- Upgraded `pg_variables`. The `DISCARD ALL` command now discards all packages and variables in `pg_variables`.
- Upgraded the `rum` module to update an error message for an error that can occur in the case when a `SELECT` query uses `ORDER BY`.

## E.4.2. Migration to Version 14.17.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

ABI versions may change between minor releases of Postgres Pro. If this is the case, and you see the `ABI mismatch` error when trying to run your extension, make sure to install a new version of the extension supplied with a new release of Postgres Pro, or recompile your third-party extension to be able to use it with the current version of Postgres Pro.

When upgrading your high-availability cluster from Postgres Pro Enterprise versions 14.12.x or lower, first disable automatic failover if it was enabled and upgrade all the standby servers, then upgrade the primary server, promote a standby, and restart the former primary (possibly with `pg_rewind`).

If you take backups using `pg_probackup` and you have previously upgraded it to version 2.8.0 Enterprise or 2.8.1 Enterprise, make sure to upgrade it to version 2.8.2 Enterprise or higher and retake a full backup after upgrade, since backups taken using those versions might be corrupted. If you suspect that your backups taken with versions 2.8.0 or 2.8.1 may be corrupted, you can validate them using version 2.8.2.

If you are migrating to the current major version of Postgres Pro Enterprise using `pg_upgrade`, and you want to keep the existing visibility map representation in `pageinspect`, you should run the `VACUUM` command before the upgrade.

Starting from Postgres Pro Enterprise 14.10.1, the privileges of `CREATEROLE` are restricted, and modification of other roles requires the role requesting the change to have the `ADMIN OPTION` permission.

It is strongly recommended to avoid migrating a cluster with 32-bit transaction IDs to Postgres Pro Enterprise versions below 14.9.2, if there are multitransactions in your database, as it may cause data corruption.

When upgrading to Postgres Pro Enterprise versions starting with 14.8.1, make sure to upgrade [pg\\_probackup](#) Enterprise to version 2.6.4 or higher since lower versions are incompatible with these Postgres Pro Enterprise versions.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.5. Postgres Pro Enterprise 14.15.1

**Release Date:** 2024-12-06

### E.5.1. Overview

This release is based on PostgreSQL 14.15 and Postgres Pro Enterprise 14.13.2. All changes inherited from PostgreSQL 14.15 are listed in [PostgreSQL 14.15 Release Notes](#). As compared with Postgres Pro Enterprise 14.13.2, this version also provides the following changes:

- Added the ability to form the `MergeAppend` operation instead of `Append`, which allows omitting additional sorting needed to ensure that the data is in fact sorted. Now `MergeAppend` is formed specifying the columns to sort by. The new ability applies only when the [enable\\_appendorpath](#) option is set to `ON`.
- Improved performance of [CFS](#) by reducing the number of invalidation messages for tables, which previously caused multiple file reopen events. Now invalidation is targeted at the specific segments affected by the garbage collector.
- Allowed transformation of correlated `IN` subqueries into joins.
- Implemented the ability to [dump](#) the state of a single backend process by sending the dump signal.
- Added a validation step to check for non-zero values in unused header fields of `*.cfm` files by `pg_upgrade`.
- Changed the error level to calculate the statistics on [vacuum](#) interrupts to `ERROR` (`PGERROR`) only. Calculating vacuum interrupts for the `PANIC` error level could cause unpredictable system behavior, and the statistics could not be calculated anyway because of the server crash.
- Fixed [cfs\\_gc\\_relation](#) to return the actual number of processed segments of the relation.
- Fixed an issue with upgrading from PostgreSQL or Postgres Pro Standard to Postgres Pro Enterprise using `pg_upgrade` when a multitransaction offset counter overflow occurred.
- Fixed the processing of 64-bit transaction IDs with proper encoding and decoding of the transaction ID.
- Fixed an issue with upgrading from PostgreSQL or Postgres Pro Standard to Postgres Pro Enterprise using `pg_upgrade` that could occur when attempting to convert heap pages to the `double xmax` page format in cases where there was insufficient free space to accommodate the special area. In the presence of multitransactions, this could lead to errors like “MultiXactId XXXXX has not been created yet” or “could not access status of transaction XXXXX”, depending on the server version. No data loss is expected as the actual conversion did not occur. Pages will now be safely converted upon first access.
- Fixed a memory leak that could occur when the [EXPLAIN](#) command's output produced over 64 columns.
- Fixed a segmentation fault, which could occur while executing the `COPY TO` command when using the [online\\_analyze](#) module.
- Fixed an issue where [EXPLAIN ANALYZE](#) showed incorrect counts of inserted and conflicted tuples during row inserts with conflicting primary keys when using `ON CONFLICT DO NOTHING`.

- Fixed an issue that could slow down query execution. The reason was that the optimizer selected a suboptimal index due to the lack of its cost estimation after removing redundant clauses with the `enable_appendorpath` option set to ON.
- Upgraded `aqo` to include the following optimizations and bug fixes:
  - Enhanced `aqo` wide search (`aqo.wide_search = on`) to utilize data from multiple neighbors simultaneously. Also, revised its interaction with `aqo.min_neighbors_for_predicting` to allow queries with fewer than the specified number of data samples to participate in wide search. Previously, such queries were excluded from consideration.
  - Fixed an array index out-of-bounds issue in the `aqo` smart statement timeout update logic, as well as incorrect statistics insertion into `aqo_query_stats` when the arrays were full. In previous releases, using `aqo_query_stat_update` with arrays of size 20 or more could lead to subsequent statistics updates being written to uncontrolled memory segments. Make sure to install the Postgres Pro on both primary and standby servers to avoid similar memory corruption problems.
- Upgraded `mamonsu` to version 3.5.9, which provides optimizations and bug fixes. Notable changes are as follows:
  - Added support for systems where `setuptools` version greater than 67.7.2 is installed.
  - Ended the use of dotted `user:group` specification at the RPM pre-install stage.
- Upgraded `multimaster` to version 1.2.0. Significantly increased catchup performance by enabling asynchronous commit operations on a lagging node syncing with the donor node, controlled by the `multimaster.enable_async_3pc_on_catchup` parameter.
- Upgraded `oracle_fdw` to version 2.7.0.
- Upgraded `orafce` to version 4.13.5.
- Upgraded `pg_filedump` to version 17.1, which specifically fixed an issue that could cause `pg_filedump` to crash with a segmentation fault when handling incomplete pages.
- Upgraded `pg_hint_plan` to version 1.4.3.
- Upgraded `pg_integrity_check` to display actual checksum values, if the checksums differ, only with the `--verbose` option.
- Upgraded `pg_portal_modify` to version 0.3.4.
- Upgraded `pg_proaudit` to provide the following optimizations and bug fixes:
  - Added logging of security events related to operations with profiles: `CREATE PROFILE`, `ALTER PROFILE`, and `DROP PROFILE`.
  - Changed the distribution of security events related to functions and stored procedures among the groups of security events: the `ALL_DDL` group now includes no events related to functions and stored procedures, `ALL_PROC` includes `CREATE`, `ALTER`, and `DROP`, while `ALL_DML` includes `EXECUTE`.
  - Fixed compatibility with the connection pooler. Previously, issues could be encountered when logging `AUTHENTICATE` and `DISCONNECT` security events.
  - Fixed logging of security events on partitioned tables by `pg_proaudit`. Now the `SELECT/UPDATE/INSERT/DELETE/TRUNCATE` events on a partitioned table get logged if logging rules imply logging of appropriate events for this table. Previously, only events on individual partitions were logged.
- Upgraded `pg_probackup` to version 2.8.5 Enterprise, which provides the following optimizations and bug fixes:
  - Enabled the output of the `version` command in the JSON format using `--format=json`.
  - Added the `--all` option to the `amcheck` command, which allows performing all the checks in a single command.

- Added support for the `include` parameter in the configuration file. The contents of the file specified in `include` gets added to the configuration file instead of this parameter.
- Added a possibility to specify an individual number of threads for execution of a backup and its subsequent validation by specifying the `--backup-threads` and `--validate-threads` option, respectively.
- Changed the priority of setting `PGDATA` and `BACKUP_PATH`. Now the values from the command-line options take precedence.
- Added validation of WAL files for backups to be merged by the `merge` command.
- An error message that was issued when the `validate` command run with the `--wal` option found an archive in the `DEGRADED` status has been replaced with a warning since backups in this status do not affect the restore correctness as a whole.
- Added support for the `--s3-config-file` option of `restore_command`. `postgresql.auto.conf` must include the `restore_command` with the `--s3-config-file` option if the backup was created with this option.
- The default value of `PG_PROBACKUP_S3_IGNORE_CERT_VER` is set to `on` according to the documentation.
- Fixed an issue that could occur if the command line was too long.
- Fixed an issue that could occur during validation or restore when the PITR from a previous timeline was performed.
- Fixed an issue that could occur when the S3 connection port was specified both in `PG_PROBACKUP_S3_PORT` and `PG_PROBACKUP_S3_HOST`. Now the value specified in `PG_PROBACKUP_S3_HOST`, together with the address, has higher priority.
- Upgraded [pgpro\\_controldata](#) to version 17.1.0.
- Upgraded [pgpro\\_stats](#) to version 1.8, which supports Postgres Pro 17. Notable changes are as follows:
  - Updated `pgpro_stats_statements` and `pgpro_stats_totals` views to include fields added to [pg\\_stat\\_statements](#). Related functions were updated accordingly.
  - Streamlined access to views and functions. Specifically, access to the `pgpro_stats_archiver`, `pgpro_stats_vacuum_database`, `pgpro_stats_vacuum_tables`, and `pgpro_stats_vacuum_indexes` views was granted to all users. Previously, these views required explicitly granting access rights. Access to execution of the `pgpro_stats_trace_reset` function, which could previously be executed by any user, was restricted to superusers.
  - Eliminated an excessive check of holding the lock when accessing the hash table of session-tracing filters.
  - Fixed processing of the `pgpro_stats.stats_temp_directory` configuration parameter. Previously after the server restart for changes to this parameter value to take effect, the fatal error “pfree called with invalid pointer” could occur when processing this parameter.
- Upgraded [pgpro\\_pwr](#) to version 4.7, which provides new features, optimizations and bug fixes. Notable changes are as follows:
  - A *subsample* feature to collect relatively fast changing data.
  - New report tables, specifically regarding session states.
  - Support for new Postgres Pro 17 statistics.
  - A possibility not to reset statistics of the statistics collecting extension during taking a sample.
  - The change of the type for the field that tracks transaction IDs in a certain table from `xid` to `text`. The use of the `xid` type could previously cause a failure of [pg\\_upgrade](#) when upgrading from Postgres Pro Standard to Postgres Pro Enterprise.
- Upgraded [pgpro\\_scheduler](#) to version 2.10, which provides the following changes:

- Fixed an issue with automatic restart of one-time jobs after job interruption.
- Fixed `schedule.get_active_jobs` to properly return the list of currently executed cron jobs.
- Fixed an issue where errors occurring during job execution were not properly logged due to a primary key constraint preventing multiple log entries.
- Fixed an issue where `at job executor` would fail when the database manager prematurely released the shared memory segment before the worker had connected to it.
- Fixed an issue where `schedule.timetable` did not display the next execution time of cron jobs with either `next_time_statement` or an array of dates. Fixed an issue with calculating next execution time for cron jobs that caused job instances to be skipped.
- Fixed an issue causing database crashes due to segmentation faults in the job executor background worker.
- Upgraded `pg_repack` to version 1.5.1.
- Upgraded `pg_wait_sampling` to provide tracking of subquery IDs and utility statements and to add the new `pg_wait_sampling.sample_cpu` parameter, which allows specifying the sampling mode that determines whether to perform sampling of on-CPU backends.
- Upgraded the PLV8 extension to version 3.2.3.
- Ensured compatibility of `postgres_fdw` with autonomous transactions.
- Upgraded `PTRACK` to prevent possible issues with PTRACK backups by setting the `ptrack.map` file for automatic deletion when PTRACK is disabled.
- Upgraded `tds_fdw` to version 2.0.4.
- Achieved compatibility with *TimescaleDB*, which is an open-source database designed to make SQL scalable for time-series data.

## E.5.2. Migration to Version 14.15.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

ABI versions may change between minor releases of Postgres Pro. If this is the case, and you see the `ABI mismatch` error when trying to run your extension, make sure to install a new version of the extension supplied with a new release of Postgres Pro, or recompile your third-party extension to be able to use it with the current version of Postgres Pro.

When upgrading your high-availability cluster from Postgres Pro Enterprise versions 14.12.x or lower, first disable automatic failover if it was enabled and upgrade all the standby servers, then upgrade the primary server, promote a standby, and restart the former primary (possibly with `pg_rewind`).

If you take backups using `pg_probackup` and you have previously upgraded it to version 2.8.0 Enterprise or 2.8.1 Enterprise, make sure to upgrade it to version 2.8.2 Enterprise or higher and retake a full backup after upgrade, since backups taken using those versions might be corrupted. If you suspect that your backups taken with versions 2.8.0 or 2.8.1 may be corrupted, you can validate them using version 2.8.2.

If you are migrating to the current major version of Postgres Pro Enterprise using `pg_upgrade`, and you want to keep the existing visibility map representation in `pageinspect`, you should run the `VACUUM` command before the upgrade.

Starting from Postgres Pro Enterprise 14.10.1, the privileges of `CREATEROLE` are restricted, and modification of other roles requires the role requesting the change to have the `ADMIN OPTION` permission.

It is strongly recommended to avoid migrating a cluster with 32-bit transaction IDs to Postgres Pro Enterprise versions below 14.9.2, if there are multitransactions in your database, as it may cause data corruption.

When upgrading to Postgres Pro Enterprise versions starting with 14.8.1, make sure to upgrade [pg\\_probackup](#) Enterprise to version 2.6.4 or higher since lower versions are incompatible with these Postgres Pro Enterprise versions.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.6. Postgres Pro Enterprise 14.13.2

**Release Date:** 2024-10-24

### E.6.1. Overview

This release is based on Postgres Pro Enterprise 14.13.1 and provides the following changes:

- Introduced various optimizations in the implementation of improved performance for subsystems on top of SLRU, including more consistent use of `int64` and acquiring the correct SLRU bank lock. The latter fixes an issue with zeroed `pg_serial` pages, which could manifest itself in “could not access status of transaction” errors.
- Fixed an issue to avoid potential stack overflow in scenarios involving a large number of subtransactions. Now when handling the process of committing a transaction, iteration is used instead of tail recursion.
- Fixed an issue that caused a terminated CFS worker to respawn with a duplicate with the same worker ID. This led to multiple instances of the same worker competing for the recovery of compressed segments.
- Fixed a race condition in committing serializable transactions.
- Fixed an issue in `pg_serial`, which could arise when the transaction counter reached values over  $2^{32}$ .
- Fixed a memory leak in `walsender` in [multimaster](#).

### E.6.2. Migration to Version 14.13.2

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.7. Postgres Pro Enterprise 14.13.1

**Release Date:** 2024-09-06

### E.7.1. Overview

This release is based on PostgreSQL 14.13 and Postgres Pro Enterprise 14.12.2. All changes inherited from PostgreSQL 14.13 are listed in [PostgreSQL 14.13 Release Notes](#). As compared with Postgres Pro Enterprise 14.12.2, this version also provides the following changes:

- Enhanced performance of segment search by implementing a new search strategy, allowing faster detection of the last segment.
- Implemented the interaction of the [PASSWORD\\_GRACE\\_TIME](#) profile parameter with the `VALID UNTIL` role attribute. Now if both of them are set, the warning about password expiration will be displayed.
- Prevented potential authentication delays due to locking by not updating role's last login time if the role's profile `USER_INACTIVE_TIME` is set to unlimited (see [Section 54.39](#) for details).

- Optimized the logic of pruning, which is now delayed until a page is nearly full, rather than relying solely on the [fill factor](#). This reduces the frequency of pruning during `UPDATE` operations, leading to better performance in tables with frequent updates.
- Fixed the following issues in [CFS](#):
  - Fixed issues related to processing of data structures in CFS by [pg\\_rewind](#). Previously, `pg_rewind` did not fully support CFS, which could result in data corruption.
  - Fixed an issue in CFS, which could cause GC worker to fail with warning “CFS GC failed to read block 0 of file X at position 0 size 0: Success”. It happened due to incorrect handling of the first MB of the data file containing only zero pages.
- Fixed a segmentation fault that could occur when a connection to the built-in [connection pooler](#) was reset before a new session was created in the backend.
- Fixed an issue with freezing 64-bit multitransaction IDs, which could manifest itself in PANIC-level errors like “xid XXX does not fit into valid range for base YYY” during [autovacuum](#).
- Fixed an issue related to suboptimal handling of `pd_prune_xid`. This issue did not result in any significant operation problems but caused unnecessary page pruning, which might have produced extra WAL records.
- Fixed an issue, which could manifest itself in errors like “invalid FSM request size”. The code was adjusted to reflect the changes in heap page structure, removing reliance on a constant related to maximum free heap page space where it is no longer applicable.
- Fixed a bug that caused the optimizer to ignore columns from query conditions. Previously, when partially using a composite index, the number of rows could be overestimated, which led to an incorrect plan creation. The bug occurred due to a malfunction of the multi-column statistics elements.
- Fixed a bug in [ANALYZE](#) that could occur because it was impossible to display the `pg_statistic` system catalog. For the fix to work, if your database has indexes with `INCLUDE` columns, after upgrading Postgres Pro, it is recommended to do another [ANALYZE](#) for these columns.
- Added support for ALT 11.
- Upgraded the [mchar](#) extension to fix a bug that caused the `mchar` and `mvarchar` data types to ignore control characters during string comparison.
- Implemented the ability to slow down transaction execution on the donor node in multimaster using the [multimaster.tx\\_delay\\_on\\_slow\\_catchup](#) configuration parameter. This is useful when a lagging node is catching up to the donor node and cannot apply changes as quickly.
- Upgraded [pg\\_filedump](#) to version 17.0, which provides optimizations and bug fixes. In particular, contents of meta pages for GIN and SP-GiST indexes are now displayed correctly, and an issue of lacking memory for encoding and decompression is resolved.
- Upgraded [pg\\_proaudit](#) to provide the following optimizations and bug fixes:
  - Improved performance and added the `pg_proaudit.max_rules_count` parameter, which allows specifying the maximum number of rules allowed.
  - Corrected support of database names including uppercase symbols by the `pg_proaudit_set_rule` function.
- Upgraded [pg\\_probackup](#) to version 2.8.3 Enterprise, which provides the following bug fixes:
  - Fixed backup validation for databases containing an OID larger than  $10^9$ . Previously, the validation status could be displayed incorrectly in such cases.
  - Fixed a bug that could occur when `pg_probackup` was run as a user included in the `postgres` group in case the database used [CFS](#).
- Fixed incorrect behavior of [pg\\_wait\\_sampling](#) when used with the extended query protocol.

- Added support for `COPY` to the [online\\_analyze](#) module.

## E.7.2. Migration to Version 14.13.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

### Important

When upgrading your high-availability cluster from Postgres Pro Enterprise versions 14.12.x or lower, first disable automatic failover if it was enabled and upgrade all the standby servers, then upgrade the primary server, promote a standby, and restart the former primary (possibly with `pg_rewind`).

If you take backups using `pg_probackup` and you have previously upgraded it to version 2.8.0 Enterprise or 2.8.1 Enterprise, make sure to upgrade it to version 2.8.2 Enterprise or higher and retake a full backup after upgrade, since backups taken using those versions might be corrupted. If you suspect that your backups taken with versions 2.8.0 or 2.8.1 may be corrupted, you can validate them using version 2.8.2.

If you are migrating to the current major version of Postgres Pro Enterprise using [pg\\_upgrade](#), and you want to keep the existing visibility map representation in [pageinspect](#), you should run the `VACUUM` command before the upgrade.

Starting from Postgres Pro Enterprise 14.10.1, the privileges of `CREATEROLE` are restricted, and modification of other roles requires the role requesting the change to have the `ADMIN OPTION` permission.

It is strongly recommended to avoid migrating a cluster with 32-bit transaction IDs to Postgres Pro Enterprise versions below 14.9.2, if there are multitransactions in your database, as it may cause data corruption.

When upgrading to Postgres Pro Enterprise versions starting with 14.8.1, make sure to upgrade [pg\\_probackup](#) Enterprise to version 2.6.4 or higher since lower versions are incompatible with these Postgres Pro Enterprise versions.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.8. Postgres Pro Enterprise 14.12.2

**Release Date:** 2024-07-01

### E.8.1. Overview

This release is based on Postgres Pro Enterprise 14.12.1 and provides the following changes:

- Fixed two issues that could occur after upgrading from PostgreSQL or Postgres Pro Standard using [pg\\_upgrade](#): fixed `xid` base calculation during heap page pruning and `xmax` calculation during page conversion from 32-bit to 64-bit format. These issues didn't result in data loss or corruption but raised PANIC-level errors.
- Fixed a segmentation fault caused by improper memory management in [CFS](#), which could occur in some corner cases where CFS garbage collector was disabled or a standby server restored WAL records for a long time (e.g. it was lagging far behind).
- Fixed a bug in the backend composite type cache management. This bug could result in a segmentation fault or produce errors like “ERROR: record type has not been registered” during the process of selectivity estimation in query planning under the following conditions:
  - The query contained at least one `JOIN` operator.

- The [enable\\_compound\\_index\\_stats](#) configuration parameter was enabled.
- The tables involved in the query had multi-column `INCLUDE` indexes.
- Upgraded orafce to version 4.10.3.
- Upgraded orafce to version 4.10.3.
- Upgraded [pg\\_probackup](#) to version 2.8.2 Enterprise, which provides the following bug fixes:
  - Fixed an OID parsing issue where databases and tablespaces with relfilenodes greater than a billion were not included in backups.
  - Fixed an issue in enabling `pg_probackup` logging with the `--log-level-file` parameter, where the parameter value was written to the configuration file, but no directory for log files was created.

## E.8.2. Migration to Version 14.12.2

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

### Important

If you take backups using `pg_probackup` and you have previously upgraded it to version 2.8.0 Enterprise or 2.8.1 Enterprise, make sure to upgrade it to version 2.8.2 Enterprise or higher and retake a full backup after upgrade, since backups taken using those versions might be corrupted. If you suspect that your backups taken with versions 2.8.0 or 2.8.1 may be corrupted, you can validate them using version 2.8.2.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.9. Postgres Pro Enterprise 14.12.1

**Release Date:** 2024-05-27

### E.9.1. Overview

This release is based on PostgreSQL 14.12 and Postgres Pro Enterprise 14.11.3. All changes inherited from PostgreSQL 14.12 are listed in [PostgreSQL 14.12 Release Notes](#). As compared with Postgres Pro Enterprise 14.11.3, this version also provides the following changes:

- Disabled the system startup timeout by setting the `TimeoutSec` parameter to 0 in `systemd`. Previously, big databases could fail to start within the specified timeout.
- Reduced logging level during a specified restore point creation at a checkpoint timeout for inactive bases only. It allows removing excessive log messages.
- Improved performance of subsystems on top of SLRU. This includes improvements for the LWLocks that changed the locking mode for the SLRU banks, so that each bank uses a separate LWLock. This results in increased scalability. Also, a new concurrency model for SLRU implementation that uses atomic reads and writes is proposed.
- Added the [cfs\\_log\\_verbose](#) configuration parameter that controls the CFS log level of defragmentation messages. It allows reducing the number of CFS messages in the log file.
- Added the [cfs\\_gc\\_lock\\_file](#) configuration parameter that sets the path to the lock file to be used to ensure running only one garbage collection worker at a time for several Postgres Pro servers.
- Added the [xml\\_parse\\_huge](#) configuration parameter that allows allocating up to 1 GB of memory for processing XML data.

- Fixed a bug resulting in error “cache lookup failed for collation 128”. Now, for the additional `INCLUDE` index columns, collation is ignored.
- Fixed two planner issues. An expression duplication issue previously caused underestimation of node selectivity and cost in some cases, which could lead to a choice of a suboptimal plan. Another issue — the selectivity overestimation for an `AppendOr` node was caused by its subnode selectivity overestimation and led to the plan cost overestimation.
- Fixed an issue of not streaming certain data to a subscriber by a logical replication after executing the `ALTER PUBLICATION pub ADD TABLE tab` command. The root cause of the issue was an insufficient interlocking between `ALTER PUBLICATION` and taking a snapshot.
- Fixed an issue with the automatic aggressive vacuum being triggered too often. Now, an aggressive vacuum scan will only occur for any table with multixact-age strictly greater than `autovacuum_multixact_freeze_max_age`.
- Added support for Astra Linux 1.8 and ended support for Astra Linux Orel 2.12, Astra Linux Smolensk 1.6.
- Added support for Red OS Murom 8 and ended support for Red OS Murom 7.2.
- Added support for Ubuntu 24.04.
- Upgraded `mamonsu` to version 3.5.8, which provides optimizations and bugfixes. Notable changes are as follows:
  - Added support for the Zabbix 6.4 API: handling of deprecated parameters for authentication requests.
  - Removed caching of the `pgsql.connections[max_connections]` metric.
  - Updated the default log rotation rules.
  - Prepared for support of Python 3.12.
  - Changed metric names of the `pg_locks` plugin. Be aware that the changes could break custom user-defined triggers and processing functions that use the `item.name` parameter.
  - Fixed type mismatch for `pgpro_stats` and `pg_wait_sampling`.
  - Fixed privileges for the `mamonsu` role created by `bootstrap`.
- Upgraded `orafce` to version 4.10.0.
- Upgraded `pg_probackup` to version 2.8.0 Enterprise, which provides new features, optimizations and bug fixes. Notable changes are as follows:
  - Added a possibility to limit the rate of disk writes using the option `--write-rate-limit=bitrate` (Mbps, Gbps).
  - Decreased the memory consumption when restoring long sequences of increments twice on average.
  - Added checksum validation for CFS files by `checkdb`.
  - Added a possibility to validate only a WAL archive.
  - Extended the use of the `--dry-run` option for all `pg_probackup` commands.
  - Made creation of a temporary slot during backups in the `STREAM` mode the default behavior unless it is specified otherwise.
  - Changed the default compression algorithm to `zstd`. If `zstd` is not supported by the system, `lz4` has the next priority. The `--compress` option now sets the default values for `--compress-level` and `--compress-algorithm`.
  - Added a possibility to specify several hosts to connect to an S3 storage.
  - Implemented a new locking technique, which enables using the locks with S3 and NFS protocols.

- Added the `pgv_exists_elem` function to [pg\\_variables](#) that checks whether an element with a key exists in a general collection.
- Upgraded [pgpro\\_stats](#) to version 1.7.1, which provides optimizations and bug fixes. Notable changes are as follows:
  - Added saving non-normalized plans to [pgpro\\_stats](#) for queries where previously no plans were saved.
  - Fixed an issue that hindered the monitoring when the `pgpro_stats_statements` view contained quite a few rows with the same values of `plan` and `queryid`, but different values of `planid`. The issue was caused by an error in parsing the plan tree containing a `T_Memoise` node.
- Fixed an error “ERROR: query failed: ERROR: tablespace “XXXX” does not exist” that could occur when the [pg\\_repack](#) command was trying to reorganize tables in a tablespace whose name started with a digit. The root cause of the issue was that `pg_repack` expected extra quotes.
- Added the `--save-fullpage` option to [pg\\_waldump](#). It allows saving full-page images included in WAL records into a given target directory.

## E.9.2. Migration to Version 14.12.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

If you are migrating to the current major version of Postgres Pro Enterprise using [pg\\_upgrade](#), and you want to keep the existing visibility map representation in [pageinspect](#), you should run the `VACUUM` command before the upgrade.

Starting from Postgres Pro Enterprise 14.10.1, the privileges of `CREATEROLE` are restricted, and modification of other roles requires the role requesting the change to have the `ADMIN OPTION` permission.

It is strongly recommended to avoid migrating a cluster with 32-bit transaction IDs to Postgres Pro Enterprise versions below 14.9.2, if there are multitransactions in your database, as it may cause data corruption.

When upgrading to Postgres Pro Enterprise versions starting with 14.8.1, make sure to upgrade [pg\\_probackup](#) Enterprise to version 2.6.4 or higher since lower versions are incompatible with these Postgres Pro Enterprise versions.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.10. Postgres Pro Enterprise 14.11.3

**Release Date:** 2024-04-08

### E.10.1. Overview

This release is based on Postgres Pro Enterprise 14.11.2 and provides the following changes:

- Increased the maximum value of the [slru\\_buffers\\_size\\_scale](#) configuration parameter to 9. In some high-load environments, the former maximum value was not sufficient and could result in query queuing and locks.
- Fixed incorrect HOT chain conversion from 32-bit to 64-bit after upgrading Postgres Pro Enterprise using `pg_upgrade`. The previous fix for this type of problem failed to account for changing the offset information after checking dead tuples.
- Fixed inconsistency of the `XMAX` value and the `XMAX_INVALID` hint bit of the tuple, which manifested itself in “missing chunk number 0 for toast value XXX in `pg_toast_XXX`” errors.

- Upgraded [pgpro\\_pwr](#) to version 4.5.
- Upgraded [pg\\_probackup](#) to version 2.7.3 Enterprise, which provides optimizations and bug fixes. Notable changes are as follows:
  - Added the `--waldir` option to the `catchup` command, which allows you to specify the directory to write WAL files to.
  - Fixed incremental restore of tables larger than 1GB. Checksum computation for file pages was fixed, so the tables will no longer be reread from the backup during restore.
  - Fixed an abnormal termination of `pg_probackup` upon a forced termination of a backup.
  - Fixed slow validation and restore of large databases by fixing file comparison. Previously, the file sorting algorithm used for the comparison could result in quadratic complexity.
  - Fixed an issue that could occur during a backup in the root of an S3 bucket.

## E.10.2. Migration to Version 14.11.3

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.11. Postgres Pro Enterprise 14.11.2

**Release Date:** 2024-03-06

### E.11.1. Overview

This release is based on Postgres Pro Enterprise 14.11.1 and provides the following changes:

- Fixed an issue of reusing subplans or alternative plans already released from memory that were previously passed by reference. This is solved by prohibiting the cleaning of expressions in memory. The issue could manifest itself in “unrecognized node” errors.
- Fixed incorrect handling of equivalence classes, which could cause [aqo](#) to ignore some plan nodes in complex queries.

### E.11.2. Migration to Version 14.11.2

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.12. Postgres Pro Enterprise 14.11.1

**Release Date:** 2024-02-21

### E.12.1. Overview

This release is based on PostgreSQL 14.11 and Postgres Pro Enterprise 14.10.1. All changes inherited from PostgreSQL 14.11 are listed in [PostgreSQL 14.11 Release Notes](#). As compared with Postgres Pro Enterprise 14.10.1, this version also provides the following changes:

- Added configuration parameters to enable getting information on crashes of a backend. The [crash\\_info](#) parameter turns on this functionality, while [crash\\_info\\_dump](#) and [crash\\_info\\_location](#) specify the contents and location of crash information files, respectively.

- Added a new configuration parameter `cfs_gc_respond_time`, which allows specifying the time interval that CFS waits for the lock to be released from a file processed by garbage collector before writing a warning to the log.
- Optimized memory consumption during selectivity estimation for each array element as compared to vanilla PostgreSQL.
- Updated the default values of `default_toast_compression` and `wal_compression` to `lz4`. It speeds up WAL and TOAST processing and reduces disk space utilization.
- Fixed incorrect HOT chain conversion from 32-bit to 64-bit after upgrading Postgres Pro Enterprise using `pg_upgrade`. Previously, it resulted in the vacuum infinite loop. The number of vacuum retries is now limited to one per tuple. When exceeded, an error is written to the log.
- Fixed segmentation fault that could occur when executing queries or using the planner with `pg_pathman` running. `pg_pathman` did not pay attention to new fields in the `RangeTblEntry` (RTE) structure, which were not correctly initialized. By making a regular copy of a parent RTE, `pg_pathman` also copied pointers to parent equivalence classes or their members. This inconsistency affected query planning and caused the error.
- Fixed the race condition between the autovacuum worker and backend processes when clearing orphaned tables, which could manifest itself in “cache lookup failed for relation” errors. Now autovacuum locks the namespaces when clearing orphaned tables.
- Fixed an issue that could occur during installation of a Postgres Pro server on Debian-based systems included in a domain with the `postgres` user.
- Fixed the output of `pg-setup`, which erroneously displayed the locale from the `LANG` environment variable at cluster initialization. Now the message about locale is not displayed at this stage.
- Fixed an issue that could occur when a `CFS` garbage collection worker process failed. Because the worker did not restart automatically, the server restart was needed to continue. Now the worker gets restarted after 10 seconds of its unavailability.
- Fixed the retention of deleted files in `CFS` by reducing the lifetime of temporary CFS files that occur during the garbage collector work or during the `VACUUM FULL` operation.
- Ended support for Rosa Enterprise Linux Server 7.
- Ended support for ROSA COBALT (server edition) based on Rosa platform 7.
- Upgraded `apache_age` to version 1.5.0.
- Upgraded `orafce` to version 4.9.2.
- Upgraded `pg_filedump` to version 16.1.
- Upgraded `pg_probackup` to version 2.7.2 Enterprise, which provides optimizations and bug fixes. Notable changes are as follows:
  - Optimized the use of memory during backups in the remote mode.
  - Fixed an issue that occurred during an incremental backup when a table that was not yet copied got removed from CFS.
  - Fixed the order of processing WAL files by the `archive-push` command when the number of WAL files exceeds the specified `--batch-size`.
  - Fixed an error “WAL segment is absent” that could occur when the size of a WAL record being logged exceeded the size of a WAL segment.
  - Fixed a bug that occurred when creating a versioned bucket in VK Cloud.
  - Fixed segmentation fault that occurred during execution of the `merge` command in S3.
- Upgraded `pg_repack` to version 1.5.0.
- Upgraded `pg_variables`, which now provides iterator functionality for any collections, as well as functions to work with general collection variables. These functions allow accessing collection ele-

ments by a key that can have either integer or text type. These enhancements facilitate migration of Oracle code that processes collections.

- Upgraded [pg\\_proaudit](#) to version 2.0, which provides the following major changes and enhancements:
  - Added new functions `pg_proaudit_set_rule` and `pg_proaudit_remove_rule` that allow creating and removing logging rules, respectively. These functions replaced `pg_proaudit_set_object`, `pg_proaudit_set_role`, `pg_proaudit_reset_object`, and `pg_proaudit_reset_role`.
  - Implemented the ability to log groups of events by specifying the respective value in the `event_type` argument.
  - Added the `comment` column in the `pg_proaudit_settings` view that displays the comment to describe the created logging rule.
  - Implemented the ability to log security events related to objects of the `PREPARED STATEMENT` type as well as events of the `DEALLOCATE`, `EXECUTE`, and `PREPARE` types.
  - Fixed an issue with incorrect logging of the `CREATE DATABASE`, `CREATE GROUP`, `CREATE ROLE`, `CREATE TABLESPACE`, and `CREATE USER` security events. Previously, these events were logged as `SUCCESS` after the syntax check and before the command execution itself. Now `SUCCESS` is written in the log when the command execution finishes, and if the command fails, it is marked as `FAILURE`.
- Upgraded [pgpro\\_stats](#) to version 1.7, which provides optimizations and bug fixes:
  - Similarly to a [pg\\_stat\\_statements](#) fix, changed [pgpro\\_stats](#) to read its “query texts” file in units of at most 1GB. Such large query text files are very unusual, but if they do occur, the previous coding would fail on Windows 64 (which rejects individual read requests of more than 2GB).
  - Implemented backward compatibility of `pgpro_stats_statements` and `pgpro_stats_totals` functions. Now a newer version of the `pgpro_stats` shared library can be safely used with old declarations of SQL functions. Previously such cases caused a server crash.
  - Fixed an issue that prevented output of database vacuuming statistics in the `pgpro_stats_vacuum_database` view.
- Upgraded [pgpro\\_pwr](#) to version 4.4, which supports [pgpro\\_stats](#) 1.7, as well as adds more interactive features and substring-based filtering to the report.
- Upgraded the PLV8 extension to version 3.2.2.

## E.12.2. Migration to Version 14.11.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

If you are migrating to the current major version of Postgres Pro Enterprise using [pg\\_upgrade](#), and you want to keep the existing visibility map representation in [pageinspect](#), you should run the `VACUUM` command before the upgrade.

Starting from Postgres Pro Enterprise 14.10.1, the privileges of `CREATEROLE` are restricted, and modification of other roles requires the role requesting the change to have the `ADMIN OPTION` permission.

It is strongly recommended to avoid migrating a cluster with 32-bit transaction IDs to Postgres Pro Enterprise versions below 14.9.2, if there are multitransactions in your database, as it may cause data corruption.

When upgrading to Postgres Pro Enterprise versions starting with 14.8.1, make sure to upgrade [pg\\_probackup](#) Enterprise to version 2.6.4 or higher since lower versions are incompatible with these Postgres Pro Enterprise versions.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.13. Postgres Pro Enterprise 14.10.1

**Release Date:** 2023-11-23

### E.13.1. Overview

This release is based on PostgreSQL 14.10 and Postgres Pro Enterprise 14.9.3. All changes inherited from PostgreSQL 14.10 are listed in [PostgreSQL 14.10 Release Notes](#). As compared with Postgres Pro Enterprise 14.9.3, this version also provides the following changes:

- Added new configuration parameters [pgpro\\_build](#), [pgpro\\_edition](#), and [pgpro\\_version](#), which report the Postgres Pro source code commit ID, edition, and server version respectively.
- Optimized memory consumption and time of performing a large number of expressions  $x=c_i$  ( $c_i$  are constants,  $i \geq 500$ ) joined by OR. The optimization is based on a replacement with ANY, such as replacement of  $x=1$  OR  $x=2$  OR  $x=3$  with  $x=ANY(\{1,2,3\})$ .
- Restricted the privileges of `CREATEROLE` and its ability to modify other roles. Previously roles with `CREATEROLE` privileges could change many aspects of any non-superuser role. Such changes, including adding members, now require the role requesting the change to have `ADMIN OPTION` permission. For example, they can now change the `CREATEDB`, `REPLICATION`, and `BYPASSRLS` properties only if they also have those permissions.
- Fixed an issue with physical replication, which could cause PANIC-level errors on replicas. Previously, pages with tuples recreated by a multitransaction were erroneously reinitialized, which resulted in `pd_multi_base` being set to zero.
- Fixed an issue with page pruning after upgrading Postgres Pro Enterprise cluster using `pg_upgrade`, which could manifest itself in “cannot fit xid into page” errors. Now updating transactions in multitransactions are taken in account so `pd_xid_base` for pages is calculated correctly.
- Fixed displaying client connection information in `pg_stat_activity` when using the built-in [connection pooler](#). Previously, the `client_addr` values were not updated for new sessions.
- Fixed an internal issue that could arise when an index relation was moved to a different namespace similarly to a plain relation.
- Fixed too long planning that could take place when `JOIN` and index increased the number of variants to consider. Planning time was reduced by indexing equivalence classes and members of them.
- Added support for ALT SP Release 10.
- Added the [apache-age](#) extension that provides graph database functionality.
- Upgraded `oracle_fdw` to version 2.6.0.
- Upgraded `orafce` to version 4.6.1.
- Upgraded [pg\\_filedump](#) to version 16.0.
- Upgraded [pgbouncer](#) to version 1.20.1.
- Upgraded [pg\\_integrity\\_check](#), which now provides three new options.
- Upgraded [pg\\_proaudit](#) to version 1.2, which provides the following changes:
  - Changed the name of the `CONNECT` events recorded by `pg_proaudit` to `AUTHENTICATE`.
  - Removed the `pg_proaudit.syslog_facility` and `pg_proaudit.syslog_ident` configuration parameters. Instead, the [syslog\\_ident](#) and [syslog\\_facility](#) parameters can be used.
  - Records in the syslog are now marked with `AUDIT` for clear identification.
  - Added the `db_name` argument for functions that add and delete the logging settings. This argument allows specifying the name of the database for which security events need to be logged. Also, the `role_oid` argument can now be passed with `NULL` to enable logging actions for all users.

- Upgraded [pgpro\\_controldata](#) to version 16.1.0.
- Upgraded [pg\\_hint\\_plan](#) to version 1.4.2.
- Upgraded [pgpro\\_stats](#) to version 1.6.3, which in particular fixed a code issue that prevented data generation for the [pgpro\\_stats\\_vacuum\\_tables view](#). Accordingly the “Database vacuum statistics” table was not included in the [pgpro\\_pwr](#) report.
- Upgraded [pg\\_probackup](#) to version 2.6.7 Enterprise, which in particular improved stability of the `catchup` command.
- Upgraded [PTRACK](#) to version 2.5.1 Enterprise.
- Fixed a segmentation fault, which could occur when the background worker of the `database manager` type was not created, but [pgpro\\_scheduler](#) assumed the opposite and continued operation.
- Upgraded `tds_fdw` to version 2.0.3.

## E.13.2. Migration to Version 14.10.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

If you are migrating to the current major version of Postgres Pro Enterprise using [pg\\_upgrade](#), and you want to keep the existing visibility map representation in [pageinspect](#), you should run the `VACUUM` command before the upgrade.

Starting from Postgres Pro Enterprise 14.10.1, the privileges of `CREATEROLE` are restricted, and modification of other roles requires the role requesting the change to have the `ADMIN OPTION` permission.

It is strongly recommended to avoid migrating a cluster with 32-bit transaction IDs to Postgres Pro Enterprise versions below 14.9.2, if there are multitransactions in your database, as it may cause data corruption.

When upgrading to Postgres Pro Enterprise versions starting with 14.8.1, make sure to upgrade [pg\\_probackup](#) Enterprise to version 2.6.4 or higher since lower versions are incompatible with these Postgres Pro Enterprise versions.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.14. Postgres Pro Enterprise 14.9.3

**Release Date:** 2023-10-05

### E.14.1. Overview

This release is based on Postgres Pro Enterprise 14.9.2 and provides the following changes:

- Added [log\\_next\\_xid\\_assign\\_threshold](#) that allows to enable logging during WAL replay when the next XID is greater than the current XID by the specified value.
- Fixed an issue with handling pages when upgrading Postgres Pro Enterprise cluster using `pg_upgrade`. This issue could manifest itself in “cannot fit xid into page” errors and lead to data corruption.
- Fixed an issue with an upgrade of Postgres Pro Enterprise cluster using `pg_upgrade`. Now empty free space map pages are not converted.

### E.14.2. Migration to Version 14.9.3

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

It is strongly recommended to avoid migrating a cluster with 32-bit transaction IDs to Postgres Pro Enterprise versions below 14.9.2, if there are multitransactions in your database, as it may cause data corruption.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.15. Postgres Pro Enterprise 14.9.2

**Release Date:** 2023-09-15

### E.15.1. Overview

This release is based on Postgres Pro Enterprise 14.9.1 and provides the following changes:

- Fixed two issues that could arise after upgrading Postgres Pro Enterprise using `pg_upgrade`. The first one resulted in incorrect conversion of multixacts from 32-bit to 64-bit transaction ID. Multixact values were erroneously incremented by 1 and files in `pg_multixact/members` and `pg_multixact/offsets` subdirectories were misaligned in some cases, which manifested itself in “found multixact XXX from before relminmxid...” errors. The second issue caused incorrect HOT chain conversion from 32-bit to 64-bit and lead to the deletion of the intermediate tuples in HOT chain, yet did not affect data.
- Fixed race conditions during resource locking caused by an oversight in a recent optimization of the [CFS](#) garbage collector, which could result in data loss. One of the symptoms was leftover `pg_depend` links referencing dropped temporary tables.
- Fixed a memory leak in [mchar](#).

### E.15.2. Migration to Version 14.9.2

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

It is strongly recommended to avoid migrating a cluster with 32-bit transaction IDs to Postgres Pro Enterprise versions below 14.9.2, if there are multitransactions in your database, as it may cause data corruption.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.16. Postgres Pro Enterprise 14.9.1

**Release Date:** 2023-08-23

### E.16.1. Overview

This release is based on PostgreSQL 14.9 and Postgres Pro Enterprise 14.8.1. All changes inherited from PostgreSQL 14.9 are listed in [PostgreSQL 14.9 Release Notes](#). As compared with Postgres Pro Enterprise 14.8.1, this version also provides the following changes:

- Added the [generic\\_plan\\_fuzz\\_factor](#) configuration parameter. This parameter sets the plan cost calculation coefficient of the planner, which increases the probability that the generic or custom plan will be selected more often.
- Added the [enable\\_appendorpath](#) configuration parameter, which enables the `Append` plan for `OR` clauses. It is useful for applications with auto-generated queries.
- Fixed [logical replication](#) to a Postgres Pro Enterprise server from servers of different editions: PostgreSQL or Postgres Pro Standard of the same or a previous version.

- Fixed a segmentation fault, which occurred during `SELECT` queries and was caused by an oversight in the previous bugfix related to self join removal optimization.
- Fixed an issue with calculating the page base for 64-bit XIDs. In some rare cases, it could lead to a transaction failure or to an incorrect `xmin`, which manifested itself in errors, such as “Fatal xid base calculation error”.
- Fixed an issue that could cause the `pg_database_size` function to return incorrect database size, which was different from the actual disk space, when using the [CFS](#). Previously, the size of CFS sparse files was calculated using the logical file size rather than the physical file size in data blocks.
- Fixed states of non-[CFS](#) background workers displayed in the `pg_stat_activity` view. The worker status is now set correctly after garbage collection.
- Fixed an issue in [pgpro\\_scheduler](#) with supervisor scheduler removing the `database manager` data before its initialization, which could lead to the manager exiting with an error “Scheduler manager XX: cannot find information about self in scheduler\_state”.
- Added support for Debian 12 and ended support for Debian 9.
- Fixed an outdated recommendation to customize a unit file in the `postgrespro-ent-14.service` file comments.
- Fixed the optimizer estimation of the number of tuples with the same hash key. The optimizer did not take into account that in a join by a large number of columns, the number of unique hash keys must rapidly grow, considered the number of hash keys to be small and finally chose merge join instead of hash join.
- Fixed usage of the `joinrel` component, which is needed for a more accurate cardinality estimation by several columns. If for some reason (for example, because of insufficient detailed statistics) `joinrel` cannot make a good prediction, Postgres Pro will not use `joinrel` in this particular case, but estimate cardinality using a regular algorithm. If `joinrel` has to estimate cardinality by a single column, a regular algorithm will also be used instead.
- Fixed a bug that did not allow storing data of the `mchar`, `nvarchar` types larger than 250 MB. Now up to 1 GB of data of these types can be stored correctly.
- Upgraded [pg\\_probackup](#) to version 2.6.5 Enterprise, which provides the following optimizations and bug fixes:
  - An attempt of a partial restore to a non-empty `PGDATA` directory now completes with an error, but a possibility of such a restore is retained with the `--destroy-all-other-dbs` flag specified.
  - Fixed inclusion of allocated but empty pages in an incremental backup.
  - Fixed point-in-time recovery issues:
    - Restore on the recovery time specified by the `pg_probackup show` command
    - Restore from backups with the `--recovery-target-timeline` and `--no-validate` options
  - Improved processing of files in compressed tablespaces by the [PTRACK](#) module.
  - Renamed the `--skip-if-exist` flag to `--skip-if-exists`.
- Upgraded [pg\\_hint\\_plan](#) to include a bugfix related to hint stack corruption.
- Upgraded [pgpro\\_pwr](#) to version 4.2, which adds interactive features to the report.
- Upgraded [PTRACK](#) to version 2.5 Enterprise.

## E.16.2. Migration to Version 14.9.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

If you are migrating to the current major version of Postgres Pro Enterprise using [pg\\_upgrade](#), and you want to keep the existing visibility map representation in [pageinspect](#), you should run the `VACUUM` command before the upgrade.

When upgrading to Postgres Pro Enterprise versions starting with 14.8.1, make sure to upgrade [pg\\_probackup](#) Enterprise to version 2.6.4 or higher since lower versions are incompatible with these Postgres Pro Enterprise versions.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.17. Postgres Pro Enterprise 14.8.1

**Release Date:** 2023-06-06

### E.17.1. Overview

This release is based on PostgreSQL 14.8 and Postgres Pro Enterprise 14.7.1. All changes inherited from PostgreSQL 14.8 are listed in [PostgreSQL 14.8 Release Notes](#). As compared with Postgres Pro Enterprise 14.7.1, this version also provides the following changes:

- Implemented lock deduplication that allows to effectively store in memory and track all exclusive locks held by a standby server's startup process during WAL replay.
- Fixed pruning logic to slightly improve performance.
- Optimized [CFS](#) garbage collector: reduced CPU costs and reads from disk during file analysis.
- Added the [unicode\\_nul\\_character\\_replacement\\_in\\_jsonb](#) configuration parameter to replace `'\u0000'` with the specified unicode character when calling a function processing JSONB.
- Improved performance of DDL operations on temporary tables. When `max_connections` is high, the costs to acquire locks for the tables that are marked `ON COMMIT DELETE ROWS` are now reduced due to the change of the locking mechanism.
- Added an operation log, which stores information about system events such as an upgrade, execution of [pg\\_resetwal](#) and so on, which is highly useful for vendor's technical support. Recording to the operation log is only done at the system level, and SQL functions are used to read it. (See [Section 9.27.12](#).)
- Fixed an issue in the [connection pooler](#), which could cause backend termination if the client aborted the connection during authentication.
- Fixed an issue with much larger [CFS](#) data files on the replica compared to the primary. Now the replica writes the files in the same way as the primary when consistent recovery state is reached.
- Fixed an internal error that occurred during a self join removal. Previously, it was not taken into account that when an expression `"A.x=B.x"` was transformed to `"A.x IS NOT NULL"`, it was necessary to correct meta parameters of the transformed expression because of its different semantics. In particular, the initial expression can be used in cases such as selection of an attribute to sort by or being a `JOIN` parametrization expression, but this is inapplicable for the transformed expression.
- Removed the deprecated configuration parameter `cfs_gc_verify_file` from `postgresql.conf`. The configuration parameter `cfs_encryption` is deprecated and will be removed in a future release.
- Added support for ROSA Chrome 2021.2.
- Ended support for Ubuntu 18.04.
- Upgraded [mamonsu](#) to version 3.5.3, which provides new features and bugfixes. Notable changes are as follows:
  - Removed the limitation that did not allow a user different from `mamonsu` to read and edit the configuration file `agent.conf`. Specifically, the `pg_probackup` plugin now works correctly when the `mamonsu` user owns the `pg_probackup` backup directory.
  - Removed metrics that conflict native Zabbix agents from Zabbix configuration file being exported.

- Fixed mamonsu choice of the default extension to collect statistics. Now when `pgpro_stats` and `pg_stat_statements` are both installed, `pgpro_stats` is correctly treated as the default one.
- Added a check that the server where mamonsu WAL plugin runs is not in recovery.
- Excluded `CREATE TABLESPACE` and `DROP TABLESPACE` from `multimaster` replication. These commands should be executed separately on each peer node.
- Upgraded `pg_hint_plan` to version 1.4.1, which provides the `hints_anywhere` parameter that allows to place hints anywhere in the query.
- Upgraded `pg_probackup` to version 2.6.4 Enterprise, which provides optimizations and bug fixes. Lower versions are incompatible with Postgres Pro Enterprise 14.8.1. Notable changes are as follows:
  - Included the `catchup` command, which was previously provided only in a test mode, in the production delivery.
  - Added optimizations for incremental backups that reduce disk read amount almost twice.
  - Improved error and warning messaging and unified the error message style.
  - Fixed issues and improved the reliability of `CFS` table merge and backup operations.
  - Fixed usability issues with the `show` command, in particular: fixed displaying the recovery time, which could sometimes not be displayed after a successful backup; made the backup time be displayed in a table view even if the backup ended with an error.
  - Fixed an error in specifying the relative path after restoring a cluster from a backup.
  - Corrected an improper assignment of backup IDs that took place in some cases.
  - Added an option to skip creation or initialization of an existing backup instance.
  - Fixed an issue with inclusion of the whole data in an incremental backup rather than only the changed data.
- Upgraded `pgpro_stats` to version 1.6, which provides new features and bugfixes:
  - Implemented tracing of application sessions, based on filters, which trigger logging the execution of queries that match filtering conditions. You can use `pgpro_stats` functions to create, update or delete query filters. (See [Section G.3.8.1](#) for details.)
  - Added functions for superuser to create views that emulate `pg_stat_statements` and `pg_stat_k-cache` extensions. Specifically, `pg_stat_statements`, `pg_stat_statements_info`, `pg_stat_k-cache` and `pg_stat_kcache_detail` views can be created. Once they are created, you can work with them as if the appropriate extension is installed. (See [Section G.3.6.1](#) for details.)
  - Added `pgpro_stats_archiver` view, which extends the `pg_stat_archiver` view by adding two fields, showing overall time that the archiver process was active and overall execution time of the archive command.
  - Implemented backward compatibility of the vacuum statistics interface. Now a newer version of the `pgpro_stats` shared library can be safely used with old declarations of SQL functions. Previously such cases caused a server crash.
  - Fixed possible server crashes that could occur due to `PGDATA` overflow when in `pgpro_stats`, one or several long queries were executed. Now instead of storing query texts in a temporary file located in the `PGDATA/pg_stat_tmp` directory, it is possible to choose the directory with the external file to store query texts by setting the value of the `pgpro_stats.stats_temp_directory` configuration parameter. If you wish, you can set this value equal to the value of the system configuration parameter `stats_temp_directory`. But keep in mind that `pgpro_stats.stats_temp_directory` can only be set at the server start.
- Upgraded `pgpro_pwr` to version 4.1.3, which supports `pgpro_stats` 1.6 and provides the following new features:
  - Added report tables “Top tables by removed all-visible/all-frozed marks”.

- Added a few new fields to the “Cluster Statistics” report table.
- Upgraded [PTRACK](#) to version 2.4.3.
- Upgraded orafce to version 4.2.6.

## E.17.2. Migration to Version 14.8.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

If you are migrating to the current major version of Postgres Pro Enterprise using [pg\\_upgrade](#), and you want to keep the existing visibility map representation in [pageinspect](#), you should run the `VACUUM` command before the upgrade.

When upgrading to Postgres Pro Enterprise versions starting with 14.8.1, make sure to upgrade [pg\\_probackup](#) Enterprise to version 2.6.4 or higher since lower versions are incompatible with these Postgres Pro Enterprise versions.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.18. Postgres Pro Enterprise 14.7.1

**Release Date:** 2023-03-07

### E.18.1. Overview

This release is based on PostgreSQL 14.7 and Postgres Pro Enterprise 14.6.1. All changes inherited from PostgreSQL 14.7 are listed in [PostgreSQL 14.7 Release Notes](#). As compared with Postgres Pro Enterprise 14.6.1, this version also provides the following changes:

- Added [enable\\_large\\_mem\\_buffers](#) that allows to copy and dump large `bytea` and `text` values. This parameter can be defined only for the current session. `--enable-large-mem-buffers` option for `pg_dump` and `pg_dumpall` was also added. `pg_restore` can restore such values by default now.
- Improved performance impacted by numerous cache resets by reducing the number of invalidation messages regarding temporary tables sent from backends to each other.
- Fixed a segmentation fault, which might have occurred in PL/pgSQL when trying to remove a separate field of a composite type upon completion of an [autonomous transaction](#).
- Added support for ROSA COBALT Server 7.9 and ended support for ROSA COBALT Server 7.3.
- Fixed suboptimal memory usage in optimizing a query that included a pretty large number of `UNION ALL` subqueries. This planner issue was due to a vanilla PostgreSQL issue with replacing placeholder variables in a special case of flattening `UNION ALL` leaf queries.
- Fixed performance degradation that was observed when running queries on a replica where [old\\_snapshot\\_threshold](#) > 0. It appeared that the issue could be encountered not only there, but was more obvious on replicas.
- Upgraded [aqo](#) to version 1.6, which provides the following new features:
  - Introduced *smart statement timeout*, which is needed to limit the execution time when manually training aqo on special queries with a poor cardinality forecast and which aqo can dynamically change during this training.
  - Added `aqo_query_stat_update`, `aqo_data_update` and `aqo_query_texts_update` functions to update or insert a record in data files underlying the respective view.
  - Added `aqo_memory_usage` function to display the memory size required for aqo.
  - Renamed `aqo_enable_query` and `aqo_disable_query` functions to `aqo_enable_class` and `aqo_disable_class`, respectively.

- Fixed an issue with [autovacuum](#) not running on unused primaries in [multimaster](#). Now logical replication correctly updates information in `pg_stat`.
- Upgraded [pg\\_probackup](#) to version 2.6.1 Enterprise, which provides the following features:
  - Optimized `pg_probackup` input/output engine to improve performance.
  - Added Simple Storage Service (S3) support for storing data in private clouds. S3 interface was tested with MinIO object storage and VK Cloud storage. Note that `pg_probackup` provides complete processing of S3 interface logging.
  - Added [CFS](#) (Compressed File System) support for incremental backups in `DELTA`, `PAGE`, and `PTRACK` modes. `PTRACK` mode requires [PTRACK](#) 2.4.0 or higher and is recommended as the fastest mode for incremental backups.
  - Added support for lz4 and zstd compression algorithm.
  - Ended support for Postgres Pro 9.6.
- Upgraded [PTRACK](#) to version 2.4.1.
- Upgraded [pgbouncer](#) to version 1.18.
- Upgraded [pgpro\\_scheduler](#) to version 2.9, which provides the following changes:
  - Fixed the `schedule.resubmit` function to save the state of the executed job correctly. Also, this function can now accept 0 as the time interval, in this case the job is resubmitted immediately after execution.
  - Fixed an issue with the `schedule.timetable` function, which previously caused an error when the function was called by any superuser other than `postgres`.
- Upgraded [pgpro\\_stats](#) to version 1.5, which provides new features and bugfixes:
  - Added computation of statistics on removal of all-frozen and all-visible marks in the visibility map.
  - Added the `pgpro_stats_vacuum_database` view, showing statistics about vacuuming each database in a cluster.
  - Fixed possible crash of a server where `pgpro_stats.track` was set to `all` that could occur when `pgpro_stats` processed a function body as a multistatement query.
  - Fixed inappropriate issuing of an “unrecognized expression node type: ...” warning in case a query plan contained a `GatherMerge` node.
  - Fixed too long execution of a query containing texts of JSON or XML documents of a special kind. The slowdown was possible because normalization of the query plan text could mistakenly include replacement of constants inside those documents.
- Upgraded [pgpro\\_pwr](#) to version 4.1.2.
- Upgraded the PLV8 extension to version 3.1.5.

## E.18.2. Migration to Version 14.7.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

If you are migrating to the current major version of Postgres Pro Enterprise using [pg\\_upgrade](#), and you want to keep the existing visibility map representation in [pageinspect](#), you should run the `VACUUM` command before the upgrade.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.19. Postgres Pro Enterprise 14.6.1

**Release Date:** 2022-12-16

### E.19.1. Overview

This release is based on PostgreSQL 14.6 and Postgres Pro Enterprise 14.5.2. All changes inherited from PostgreSQL 14.6 are listed in [PostgreSQL 14.6 Release Notes](#). As compared with Postgres Pro Enterprise 14.5.2, this version also provides the following changes:

- Added [ignore\\_event\\_trigger](#) that allows to disable [event triggers](#) temporarily.
- Added [slru\\_buffers\\_size\\_scale](#) that allows to scale the size of SLRU shared memory buffers. Note that the buffer sizes changed due to this improvement.
- Improved garbage collection logic in [CFS](#). Now percent of garbage is calculated based on file size rounded to 4 kB (typical filesystem block size) instead of raw file size, which prevents frequent defragmentation of small files.
- Added support for Elbrus CPU architecture through ALT 9/10 for e2kv3/e2kv4, ALT 8.2 SP for e2kv3/e2kv4 and Astra Linux Leningrad 8.1 operating systems. You are recommended to use the 5.4.182-mcst-e8c-alt3.22.1 Linux kernel or newer when running ALT 10 for e2kv3/e2kv4.
- Fixed an issue with password authentication when using the [connection pooler](#), which manifested itself in “authentication identifier set more than once” errors.
- Fixed an issue with physical replication, which could lead to a replica crash in rare cases. Previously, WAL records on update and init of heap pages did not contain `pd_multi_base` so incorrect `xmax` values could be set.
- Fixed huge selectivity overestimation observed in rare cases, which could result in a sequential scan of a whole relation instead of a quick index scan, so certain queries were executed much more slowly than expected. The issue was due to an oversight in a recent optimization of selectivity estimation.
- Fixed bursts in the `checkpoint_req` counter of the [pg\\_stat\\_bgwriter](#) view on a replica that occurred from time to time due to a series of unsuccessful attempts to create a restartpoint. The fix checks in advance whether an attempt to create a restartpoint will fail and thus prevents from making obviously unsuccessful attempts. Note that the issue did not cause excessive consumption of system resources even before it was fixed.
- Fixed compatibility of [in\\_memory](#) with autonomous transactions.
- Fixed an issue in [psql](#), which mistakenly treated the `\duS` and `\duS+` meta-commands as invalid. Both meta-commands list database roles, including system roles, with a different level of detail, and correctly processed `\dgS+` and `\du+S` (respectively) could be used instead even before the issue was fixed.
- Upgraded [aqo](#) to version 1.5, which contains bugfixes and the following changes:
  - Switched to storing the knowledge base on disk outside of the database. Previously it was stored in Postgres Pro tables.
  - Made aqo relocatable.
  - Added functions to analyze the quality of query planning.
  - Added a possibility to learn from partially completed queries, namely, from those that timed out (see [statement\\_timeout](#)).
  - Made aqo use the same query ID as other extensions. So aqo and [pg\\_stat\\_statements](#) can be used simultaneously, sharing the same query IDs.
  - Enabled aqo work with temporary tables.
  - Fixed a few memory leaks.
  - Added alpha version of a new feature: search by neighbors (off by default). It allows applying knowledge to newly added queries with a different structure.
- Upgraded [mamonsu](#) to version 3.5.2, which provides new features and bugfixes. Notable changes are as follows:

- Added autovacuum utilization metrics.
- Added Zabbix macros based on plugin parameters from the configuration file, so that triggers can now be dynamically changed directly in Zabbix without updating the configuration file and restarting mamonsu.
- The [multimaster](#) extension is considered as ready-to-use. Notable changes are as follows:
  - Implemented transaction deadlock prevention mechanism managed by the [multimaster.deadlock\\_prevention](#) configuration parameter. It allows to avoid situations when transactions might not actually run in case of many conflicts due to long deadlock resolution time.
  - Fixed states of [multimaster](#) apply workers displayed in the `pg_stat_activity` view. After applying transactions, the worker status is now set to `Idle` instead of `Active`.
  - Fixed an issue, which could result in isolation of all [multimaster](#) cluster nodes after dropping any node and adding a new node to the cluster.
- Added the `oracle_fdw` extension to Windows versions of Postgres Pro.
- Upgraded [pg\\_probackup](#) to version 2.5.10, which provides optimizations and bugfixes. Notable changes are as follows:
  - Optimized `*.cfm` files backup by truncating trailing zeroes.
  - Fixed an issue with `checkdb --amcheck`, which previously completed with an error when the checked database contained partitioned indexes.
  - Fixed a backup failure on a replica that occurred because the version of the `pg_probackup` agent running there was different from that on the primary.
- Upgraded [pgpro\\_pwr](#) to version 4.1, which mainly adds JIT-related statistics to report tables.
- Upgraded [pgpro\\_scheduler](#) to version 2.8. This version introduces the [schedule.timetable\(\)](#) function, which returns all the jobs, both scheduled and one-time, within the specified time interval.
- Upgraded [pgpro\\_stats](#) to version 1.4.3, which provides bugfixes. In particular:
  - Fixed possible server crashes that could occur during query text normalization when an extended protocol was used.
- Added `tds_fdw` extension that provides a foreign data wrapper to connect to Microsoft SQL Server and other databases that use the Tabular Data Stream (TDS) protocol.

## E.19.2. Migration to Version 14.6.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

If you are migrating to the current major version of Postgres Pro Enterprise using [pg\\_upgrade](#), and you want to keep the existing visibility map representation in [pageinspect](#), you should run the `VACUUM` command before the upgrade.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.20. Postgres Pro Enterprise 14.5.2

**Release Date:** 2022-10-06

### E.20.1. Overview

This release is based on Postgres Pro Enterprise 14.5.1. and provides the following changes:

- Fixed a bug in the logic of epoch shifting. The previous bug fix, which involved delta page replication, might have interfered with another issue, resulting in data corruption. Now full page replication is triggered.

- Fixed a segmentation fault, which could occur on a replica due to inconsistent page fragmentation. During pruning, actions on dead tuples could differ on the primary and the standby upon WAL re-play, causing page inconsistency.
- Fixed an issue with queries that could time out due to long lock waits. Previously, index type names were locked in temporary tables during index creation.

## E.20.2. Migration to Version 14.5.2

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

### Important

If you have previously migrated to Postgres Pro Enterprise 14.5.1, or suspect data corruption on your replica, it is strongly recommended that you recreate the replica.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.21. Postgres Pro Enterprise 14.5.1

**Release Date:** 2022-09-08

### E.21.1. Overview

This release is based on PostgreSQL 14.5 and Postgres Pro Enterprise 14.4.1. All changes inherited from PostgreSQL 14.5 are listed in [PostgreSQL 14.5 Release Notes](#). As compared with Postgres Pro Enterprise 14.4.1, this version also provides the following changes:

- Fixed a segmentation fault, which occurred during logical replication when a trigger fired on data modification on the replica, and an error was thrown inside the trigger function.
- Fixed various issues in `pg_upgrade`. In particular, now free space maps and visibility maps are handled correctly during the upgrade.
- Fixed a bug in the logic of epoch shifting, which didn't take into account the `XMAX_INVALID` hint bit of the tuple. Previously, it could lead to a sudden increase of the current transaction ID.
- Resolved an issue that caused an error “duplicate key value violates unique constraint” when indexing a database in multiple threads. Now the chosen name of a type being created for the index gets locked to avoid choosing the same name in a parallel process.
- Resolved an issue in the planner's use of the compound indexes statistics: the optimizer reduced the cost prediction accuracy for a query plan if in the `WHERE` clause of the query, values of different types were compared (for example: `integer` and `numeric`, `text` and `name`). Sometimes, for certain combinations of the compared types and values, the issue could cause a server crash.
- Added support for Red Hat Enterprise Linux 9 and its derivatives: Rocky Linux 9, Oracle Linux 9, and AlmaLinux 9.
- Upgraded [mamonsu](#) to version 3.5.1. Notable changes are as follows:
  - Enabled mamonsu plugins to use [pgpro\\_stats](#) to collect statistics.
  - Resolved the security issue of exposing passwords through the configuration file. Only `mamonsu` user can access `agent.conf` now.
  - Fixed metrics computation that caused “float division by zero” errors in the mamonsu STATEMENTS plugin.
- Upgraded [pg\\_probackup](#) to version 2.5.7, which provides the following new features and bugfixes:

- Enabled output of logs in the JSON format by adding new logging options.
- Added an option to explicitly specify the directory where the `restore` command should restore WAL records.
- Changed the level of detail of logging some messages of `pg_probackup` commands to add user convenience to reading logs.
- Fixed `pg_probackup` hanging that could occur when the `ControlMaster` option was specified in the `SSH config` file. Now the value of `ControlMaster` is explicitly set to “no”.
- Upgraded `pgpro_pwr` to version 4.0.
- Added the `oracle_fdw` package for Red OS Murom 7.3.

### E.21.2. Migration to Version 14.5.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

If you are migrating to the current major version of Postgres Pro Enterprise using `pg_upgrade`, and you want to keep the existing visibility map representation in `pageinspect`, you should run the `VACUUM` command before the upgrade.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.22. Postgres Pro Enterprise 14.4.1

**Release Date:** 2022-06-21

### E.22.1. Overview

This release is based on PostgreSQL 14.4 and Postgres Pro Enterprise 14.2.1. All changes inherited from PostgreSQL 14.4 are listed in [PostgreSQL 14.4 Release Notes](#). As compared with Postgres Pro Enterprise 14.2.1, this version also provides the following changes:

- Changed the algorithm of composite type name generation. This fixes an issue in the code of vanilla PostgreSQL, which strictly limits the number of tables with the same long prefix in names.
- Added support for Ubuntu 22.04.
- Ended support for OSnova 2.0.
- Made the `pg_freespacemap` `pg_freespace` function display the correct amount of free space on pages for tables in CFS tablespaces. The function is now implemented in C instead of SQL used before.
- Upgraded `pg_probackup` to version 2.5.6, which provides the following new features and bugfixes as compared to version 2.5.5:
  - Added the `--dry-run` flag to the `catchup` command to allow you to estimate the size of data files to be transferred, but make no changes on disk.
  - Changed the level of detail of logging some `catchup` messages for user convenience of log reading.
  - Fixed a bug that prevented correct rereading of a block after a message “File: ... blknum ... have wrong checksum, try again” was issued.
- Upgraded `PTRACK` to version 2.3.0, optimizing PTRACK map loading, which previously in some cases could considerably slow down overall database loading. A substantial speed-up is observed for large-size maps.
- Upgraded `pgpro_stats` to version 1.4, which provides the following new features and bugfixes:

- Added `pgpro_stats_vacuum_tables` and `pgpro_stats_vacuum_indexes` views, which show statistics about vacuuming tables and indexes, respectively. Functions with the same names, which define these views for any specified database and table/index, are also added and can return statistics about vacuuming all tables/indexes in the specified database too.
- Fixed a bug in extra shared memory allocation. The size of this memory was calculated with an error, which could cause memory corruption, incorrect computation of statistics or even a server crash.
- Fixed an issue that caused a server crash when queries that only differ in constants contained in the query text were sent one after another through the extended query protocol.
- Upgraded [pgpro\\_pwr](#) to version 3.9, which provides the following new features and bugfixes:
  - Added statistics on invalidation messages and on vacuuming tables and indexes to the report.
  - Optimized retention handling for obsolete dictionary entries in the `pgpro_pwr` historical repository.
  - Fixed the type of value in calculating the wait time while taking a sample. This prevents a yet unlikely integer overflow error.
- Renamed the `vops`-specific `unnest()` function with conflicting definition to `vops_unnest()`.

## E.22.2. Migration to Version 14.4.1

If you are upgrading from a Postgres Pro Enterprise release based on the same PostgreSQL major version, it is enough to install the new version into your current installation directory.

To migrate from PostgreSQL, as well as Postgres Pro Standard or Postgres Pro Enterprise based on a previous PostgreSQL major version, see the [migration instructions for version 14](#).

## E.23. Postgres Pro Enterprise 14.2.1

**Release Date:** 2022-05-13

### E.23.1. Overview

This release is based on PostgreSQL 14.2 and includes all the new features introduced in PostgreSQL 14, as well as bug fixes implemented in PostgreSQL 14.1 and 14.2 updates. For the detailed description, see [PostgreSQL 14](#), [PostgreSQL 14.1](#) and [PostgreSQL 14.2](#) Release Notes, respectively.

For the list of extension modules and utilities specific to Postgres Pro Enterprise, as well as the main user-visible core changes over vanilla PostgreSQL, see [Section 2](#). As compared to Postgres Pro Enterprise 13.6.1, the following differences are worth mentioning:

- Implemented [event triggers](#), which fire when an authenticated user logs in. For example, this feature can be used for verifying the connection and assigning roles according to circumstances, or for session data initialization.
- Inherited the vanilla implementation of [periodic verification](#) of client-server connection during query execution. The corresponding `client_connection_check_interval` parameter is effectively disabled by default now.
- Fixed a security bug (CVE-2022-1552).
- Removed the infrastructure for minor version upgrades without a server restart as a different approach to this feature is to be considered in the foreseeable future.
- Implemented the evaluation-only version of the [multimaster](#) extension for now.
- Implemented collecting statistics about vacuuming tables and indexes. The collected information is displayed in [pgpro\\_stats](#) views.
- Upgraded [pgpro\\_pwr](#) to version 3.8, which particularly adds statistics on invalidation messages and on vacuuming tables and indexes to the report.

## E.23.2. Migration to Version 14

You can migrate to Postgres Pro Enterprise 14 from the same or a previous version of PostgreSQL (that is supported by the upgrade method chosen) or Postgres Pro Standard/Postgres Pro Standard Certified and from a previous version of Postgres Pro Enterprise/Postgres Pro Enterprise Certified. The same holds for migration to Postgres Pro Enterprise Certified 14. See [Section 18.6](#) for the methods to upgrade your database cluster. Consult the Postgres Pro Enterprise support team if you experience issues during migration. Backward migration is not supported. Note that migration from Postgres Pro Enterprise to Postgres Pro Enterprise Certified of the same major version (or vice versa) is an update between Postgres Pro compatible versions (see [Section 18.6](#) for more details).

To migrate from PostgreSQL, Postgres Pro Standard, or Postgres Pro Enterprise release based on a previous PostgreSQL major version, make sure to install its latest available minor version and then perform a dump/restore using [pg\\_dumpall](#) or use the [pg\\_upgrade](#) utility:

- If you choose to run `pg_upgrade`, make sure to initialize the new database cluster with compatible parameters. In particular, pay attention to the provider of the default collation and the [checksum](#) settings in the cluster you are migrating from. If `pg_upgrade` creates any SQL files in its current directory, run these files to complete the upgrade.
- If you are opting for a dump/restore, do not forget to use the `--add-collprovider` option to correctly choose the provider for the default collation of the migrated database.

To find out the default collation and its provider in the original cluster, see the `datcollate` value for the `template0` database in the [pg\\_database](#) catalog. If you are upgrading from a version where provider of the default collation is not specified, use `libc` provider if upgrading from vanilla PostgreSQL, and omit the provider if upgrading from earlier versions of Postgres Pro.

When migrating from PostgreSQL or Postgres Pro Standard, make sure to pay special attention to implementation specifics of [64-bit transaction IDs](#). If you have used explicit casts to 32-bit integers when handling transaction IDs, you have to replace them with casts to `bigint` since 64-bit transaction IDs are of the `bigint` type.

### Note

To avoid conflicts on Linux systems, do not use the `postgrespro-ent-14` package to install the new Postgres Pro binaries. Use the individual packages instead. In this case, server autostart needs to be enabled manually, if required. For details on the available packages and installation instructions, see [Chapter 17](#).

For other upgrade requirements imposed by vanilla PostgreSQL, see [Section E.44](#).

## E.24. Release 14.20

**Release date:** 2025-11-13

This release contains a variety of fixes from 14.19. For information about new features in major release 14, see [Section E.44](#).

### E.24.1. Migration to Version 14.20

A dump/restore is not required for those running 14.X.

However, if you are upgrading from a version earlier than 14.19, see [Section E.25](#).

### E.24.2. Changes

- Check for `CREATE` privileges on the schema in `CREATE STATISTICS` (Jelte Fennema-Nio)

This omission allowed table owners to create statistics in any schema, potentially leading to unexpected naming conflicts.

The PostgreSQL Project thanks Jelte Fennema-Nio for reporting this problem. (CVE-2025-12817)

- Avoid integer overflow in allocation-size calculations within libpq (Jacob Champion)

Several places in libpq were not sufficiently careful about computing the required size of a memory allocation. Sufficiently large inputs could cause integer overflow, resulting in an undersized buffer, which would then lead to writing past the end of the buffer.

The PostgreSQL Project thanks Aleksey Solovlev of Positive Technologies for reporting this problem. (CVE-2025-12818)

- Further fix processing of character classes within `SIMILAR TO` regular expressions (Laurenz Albe)

The previous fix for translating `SIMILAR TO` pattern matching expressions to POSIX-style regular expressions broke a corner case that formerly worked: if there is an escape character right after the opening bracket and then a closing bracket right after the escape sequence (for example `[\w]`), the closing bracket was no longer seen as terminating the character class.

- Fix parsing of aggregate functions whose arguments contain a sub-select with a `FROM` reference to a CTE outside the aggregate function (Tom Lane)

Such a CTE reference must act like a outer-level column reference when determining the aggregate's semantic level; but it was not being accounted for, leading to obscure planner or executor errors.

- Fix “no relation entry for relid” errors in corner cases while estimating SubPlan costs (Richard Guo)
- Remove faulty assertion in btree index cleanup (Peter Geoghegan)
- Fix possible infinite loop in GIN index scans with multiple scan conditions (Tom Lane)

GIN can handle scan conditions that can reject non-matching entries but are not useful for searching for relevant entries, for example a `tsquery` clause like `!term`. But such a condition must not be first in the array of scan conditions. The code failed to ensure that in all cases, with the result that a query having a mix of such conditions with normal conditions might work or not depending on the order in which the conditions were given in the query.

- Ensure that GIN index scans can be canceled (Tom Lane)

Some code paths were capable of running for a long time without checking for interrupts.

- Ensure that BRIN autosummarization provides a snapshot for index expressions that need one (Álvaro Herrera)

Previously, autosummarization would fail for such indexes, and then leave placeholder index tuples behind, causing the index to bloat over time.

- Fix integer-overflow hazard in BRIN index scans when the table contains close to  $2^{32}$  pages (Sunil S)

This oversight could result in an infinite loop or scanning of unneeded table pages.

- Fix incorrect zero-extension of stored values in JIT-generated tuple deforming code (David Rowley)

When not using JIT, the equivalent code does sign-extension not zero-extension, leading to a different Datum representation of small integer data types. This inconsistency was masked in most cases, but it is known to lead to “could not find memoization table entry” errors when using Memoize plan nodes, and there might be other symptoms.

- Add missing EvalPlanQual rechecks for TID Scan and TID Range Scan plan nodes (Sophie Alpert, David Rowley)

This omission led to possibly not rechecking a condition on `ctid` during concurrent-update situations, causing the update's behavior to vary depending on which plan type had been selected.

- Fix EvalPlanQual handling of foreign or custom joins that do not have an alternative local-join plan prepared for EPQ (Masahiko Sawada, Etsuro Fujita)

In such cases the foreign or custom access method should be invoked normally, but that did not happen, typically leading to a crash.

- Avoid duplicating hash partition constraints during `DETACH CONCURRENTLY` (Haiyang Li)

`ALTER TABLE DETACH PARTITION CONCURRENTLY` was written to add a copy of the partitioning constraint to the now-detached partition. This was misguided, partially because non-concurrent `DETACH` doesn't do that, but mostly because in the case of hash partitioning the constraint expression contains references to the parent table's OID. That causes problems during dump/restore, or if the parent table is dropped after `DETACH`. In v19 and later, we'll no longer create any such copied constraints at all. In released branches, to minimize the risk of unforeseen consequences, only skip adding a copied constraint if it is for hash partitioning.

- Disallow generated columns in partition keys (Jian He, Ashutosh Bapat)

This was already not allowed, but the check missed some cases, such as where the column reference is implicit in a whole-row reference.

- Disallow generated columns in `COPY ... FROM ... WHERE` clauses (Peter Eisentraut, Jian He)

Previously, incorrect behavior or an obscure error message resulted from attempting to reference such a column, since generated columns have not yet been computed at the point where `WHERE` filtering is done.

- Fix visibility checking for statistics objects in `pg_temp` (Noah Misch)

A statistics object located in a temporary schema cannot be named without schema qualification, but `pg_statistics_obj_is_visible()` missed that memo and could return “true” regardless. In turn, functions such as `pg_describe_object()` could fail to schema-qualify the object's name as expected.

- Fix memory leakage in hashed subplans (Haiyang Li)

Any memory consumed by the hash functions used for hashing tuples constituted a query-lifespan memory leak. One way that could happen is if the values being hashed require de-toasting.

- Add missing replica identity checks in `MERGE` and `INSERT ... ON CONFLICT DO UPDATE` (Zhijie Hou)

If `MERGE` may require update or delete actions, and the target table publishes updates or deletes, insist that it have a `REPLICA IDENTITY` defined. Failing to require this can silently break replication. Likewise, `INSERT` with an `UPDATE` option must require `REPLICA IDENTITY` if the target table publishes either inserts or updates.

- Avoid deadlock during `DROP SUBSCRIPTION` when publisher is on the same server as subscriber (Dilip Kumar)
- Fix incorrect reporting of replication lag in `pg_stat_replication` view (Fujii Masao)

If any standby server's replay LSN stopped advancing, the `write_lag` and `flush_lag` columns would eventually stop updating.

- Avoid duplicative log messages about invalid `primary_slot_name` settings (Fujii Masao)
- Remove the unfinished slot state file after failing to write a replication slot's state to disk (Michael Paquier)

Previously, a failure such as out-of-disk-space resulted in leaving a temporary `state.tmp` file behind. That's problematic because it would block all subsequent attempts to write the state, requiring manual intervention to clean up.

- Avoid unwanted WAL receiver shutdown when switching from streaming to archive WAL source (Xuneng Zhou)

During a timeline change, a standby server's WAL receiver should remain alive, waiting for a new WAL streaming start point. Instead it was repeatedly shutting down and immediately getting restarted, which could confuse status monitoring code.

- Avoid failures in logical replication due to chance collisions of file numbers between regular and temporary tables (Vignesh C)

This low-probability problem manifested as transient errors like “unexpected duplicate for table-space *X*, relfilenode *Y*”. `contrib/autoprewarm` was also affected. A side-effect of the fix is that the SQL function `pg_filenode_relation()` will now ignore temporary tables.

- Avoid assertion failure when trying to release a replication slot in single-user mode (Hayato Kuroda)
- Fix incorrect printing of messages about failures in checking whether the user has Windows administrator privilege (Bryan Green)

This code would have crashed or at least printed garbage. No such cases have been reported though, indicating that failure of these system calls is extremely rare.

- Avoid startup failure on macOS and BSD platforms when there is a collision with a pre-existing semaphore set (Tom Lane)

If the pre-existing set has fewer semaphores than we asked for, these platforms return `EINVAL` not `EEXIST` as our code expected, resulting in failure to start the database.

- Fix false memory-context-checking warnings in debug builds on 64-bit Windows (David Rowley)
- Correctly handle `GROUP BY DISTINCT` in PL/pgSQL assignment statements (Tom Lane)

The parser failed to record the `DISTINCT` option in this context, so that the command would act as if it were plain `GROUP BY`.

- Avoid leaking memory when handling a SQL error within PL/Python (Tom Lane)

This fixes a session-lifespan memory leak introduced in our previous minor releases.

- Fix libpq's trace output of characters with the high bit set (Ran Benita)

On platforms where `char` is considered signed, the output included unsightly `\xffffffff` decoration.

- Fix libpq's handling of socket-related errors on Windows within its GSSAPI logic (Ning Wu, Tom Lane)

The code for encrypting/decrypting transmitted data using GSSAPI did not correctly recognize error conditions on the connection socket, since Windows reports those differently than other platforms. This led to failure to make such connections on Windows.

- In `pg_dump`, dump security labels on subscriptions and event triggers (Jian He, Fujii Masao)

Labels on these types of objects were previously missed.

- Fix `pg_dump`'s sorting of default ACLs and foreign key constraints (Kirill Reshke, Álvaro Herrera)

Ensure consistent ordering of these database object types, as was already done for other object types.

- In `pg_dump`, label comments for separately-dumped domain constraints with the proper dependency (Noah Misch)

This error could lead to parallel `pg_restore` attempting to create the comment before the constraint itself has been restored.

- In `pg_restore`, skip comments and security labels for publications and subscriptions that are not being restored (Jian He, Fujii Masao)

Do not emit `COMMENT` or `SECURITY LABEL` commands for these objects when `--no-publications` or `--no-subscriptions` is specified.

- Fix assorted errors in the data compression logic in `pg_dump` and `pg_restore` (Daniel Gustafsson, Tom Lane)

Error checking was missing or incorrect in several places, and there were also portability issues that would manifest on big-endian hardware. These problems had been missed because this code is only used to read compressed TOC files within directory-format dumps. `pg_dump` never produces such a dump; the case can be reached only by manually compressing the TOC file after the fact, which is a supported thing to do but very uncommon.

- Fix `pgbench` to error out cleanly if a `COPY` operation is started (Anthonin Bonnefoy)

`pgbench` doesn't intend to support this case, but previously it went into an infinite loop.

- Fix `pgbench`'s reporting of multiple errors (Yugo Nagata)

In cases where two successive `PQgetResult` calls both fail, `pgbench` might report the wrong error message.

- Ensure that `contrib/pg_buffercache` functions can be canceled (Satyanarayana Narlapuram, Yuhang Qiu)

Some code paths were capable of running for a long time without checking for interrupts.

- Fix `contrib/pg_prewarm`'s privilege checks for indexes (Ayush Vatsa, Nathan Bossart)

`pg_prewarm()` requires `SELECT` privilege on relations to be prewarmed. However, since indexes have no SQL privileges of their own, this resulted in non-superusers being unable to prewarm indexes. Instead, check for `SELECT` privilege on the index's table.

- Make `contrib/pgstattuple` more robust about empty or invalid index pages (Nitin Motiani)

Count all-zero pages as free space, and ignore pages that are invalid according to a check of the page's special-space size. The code for btree indexes already counted all-zero pages as free, but the hash and gist code would error out, which has been found to be much less user-friendly. Similarly, make all three cases agree on ignoring corrupted pages rather than throwing errors.

- Harden our read and write barrier macros to satisfy Clang (Thomas Munro)

We supposed that `__atomic_thread_fence()` is a sufficient barrier to prevent the C compiler from re-ordering memory accesses around it, but it appears that that's not true for Clang, allowing it to generate incorrect code for at least RISC-V, MIPS, and LoongArch machines. Add explicit compiler barriers to fix that.

- Fix building with LLVM version 21 and later (Holger Hoffstätte)
- Fix PGXS build infrastructure to support building NLS `po` files for extensions (Ryo Matsumura)

## E.25. Release 14.19

**Release date:** 2025-08-14

This release contains a variety of fixes from 14.18. For information about new features in major release 14, see [Section E.44](#).

### E.25.1. Migration to Version 14.19

A dump/restore is not required for those running 14.X.

However, if you have any BRIN `numeric_minmax_multi_ops` indexes, it is advisable to reindex them after updating. See the fourth changelog entry below.

Also, if you are upgrading from a version earlier than 14.18, see [Section E.26](#).

## E.25.2. Changes

- Tighten security checks in planner estimation functions (Dean Rasheed)

The fix for CVE-2017-7484, plus followup fixes, intended to prevent leaky functions from being applied to statistics data for columns that the calling user does not have permission to read. Two gaps in that protection have been found. One gap applies to partitioning and inheritance hierarchies where RLS policies on the tables should restrict access to statistics data, but did not.

The other gap applies to cases where the query accesses a table via a view, and the view owner has permissions to read the underlying table but the calling user does not have permissions on the view. The view owner's permissions satisfied the security checks, and the leaky function would get applied to the underlying table's statistics before we check the calling user's permissions on the view. This has been fixed by making security checks on views occur at the start of planning. That might cause permissions failures to occur earlier than before.

The PostgreSQL Project thanks Dean Rasheed for reporting this problem. (CVE-2025-8713)

- Prevent `pg_dump` scripts from being used to attack the user running the restore (Nathan Bossart)

Since dump/restore operations typically involve running SQL commands as superuser, the target database installation must trust the source server. However, it does not follow that the operating system user who executes `psql` to perform the restore should have to trust the source server. The risk here is that an attacker who has gained superuser-level control over the source server might be able to cause it to emit text that would be interpreted as `psql` meta-commands. That would provide shell-level access to the restoring user's own account, independently of access to the target database.

To provide a positive guarantee that this can't happen, extend `psql` with a `\restrict` command that prevents execution of further meta-commands, and teach `pg_dump` to issue that before any data coming from the source server.

The PostgreSQL Project thanks Martin Rakhmanov, Matthieu Denais, and RyotaK for reporting this problem. (CVE-2025-8714)

- Convert newlines to spaces in names included in comments in `pg_dump` output (Noah Misch)

Object names containing newlines offered the ability to inject arbitrary SQL commands into the output script. (Without the preceding fix, injection of `psql` meta-commands would also be possible this way.) CVE-2012-0868 fixed this class of problem at the time, but later work reintroduced several cases.

The PostgreSQL Project thanks Noah Misch for reporting this problem. (CVE-2025-8715)

- Fix incorrect distance calculation in BRIN `numeric_minmax_multi_ops` support function (Peter Eisentraut, Tom Lane)

The results were sometimes wrong on 64-bit platforms, and wildly wrong on 32-bit platforms. This did not produce obvious failures because the logic is only used to choose how to merge values into ranges; at worst the index would become inefficient and bloated. Nonetheless it's recommended to reindex any BRIN indexes that use the `numeric_minmax_multi_ops` operator class.

- Avoid regression in the size of XML input that we will accept (Michael Paquier, Erik Wienhold)

Our workaround for a bug in early 2.13.x releases of `libxml2` made use of a code path that rejects text chunks exceeding 10MB, whereas the previous coding did not. Those early releases are presumably extinct in the wild by now, so revert to the previous coding.

- Allow tables with statement-level triggers to become partitions or inheritance children (Etsuro Fujita)

We do not allow partitions or inheritance child tables to have row-level triggers with transition tables, because an operation on the whole inheritance tree would need to maintain a separate transition table for each such child table. But that problem does not apply for statement-level triggers, because only the parent's statement-level triggers will be fired. The code that checks whether an existing table can become a partition or inheritance child nonetheless rejected both kinds of trigger.

- Disallow collecting transition tuples from child foreign tables (Etsuro Fujita)

We do not support triggers with transition tables on foreign tables. However, the case of a partition or inheritance child that is a foreign table was overlooked. If the parent has such a trigger, incorrect transition tuples were collected from the foreign child. Instead throw an error, reporting that the case is not supported.

- Fix a potential deadlock during `ALTER SUBSCRIPTION ... DROP PUBLICATION` (Ajin Cherian)

Ensure that server processes acquire catalog locks in a consistent order during replication origin drops.

- Shorten the race condition window for creating indexes with conflicting names (Tom Lane)

When choosing an auto-generated name for an index, avoid conflicting with not-yet-committed `pg_class` rows as well as fully-valid ones. This avoids possibly choosing the same name as some concurrent `CREATE INDEX` did, when that command is still in process of filling its index, or is done but is part of a not-yet-committed transaction. There's still a window for trouble, but it's only as long as the time needed to validate a new index's parameters and insert its `pg_class` row.

- Prevent usage of incorrect `VACUUM` options in some cases where multiple tables are vacuumed in a single command (Nathan Bossart, Michael Paquier)

The `TRUNCATE` and `INDEX_CLEANUP` options of one table could be applied to others.

- Fix processing of character classes within `SIMILAR TO` regular expressions (Laurenz Albe)

The code that translates `SIMILAR TO` pattern matching expressions to POSIX-style regular expressions did not consider that square brackets can be nested. For example, in a pattern like `[[:alpha:]]%_`, the code treated the `%` and `_` characters as metacharacters when they should be literals.

- When deparsing queries, always add parentheses around the expression in `FETCH FIRST expression ROWS WITH TIES` clauses (Heikki Linnakangas)

This avoids some cases where the deparsed result wasn't syntactically valid.

- Limit the checkpoint process's `fsync` request queue size (Alexander Korotkov, Xuneng Zhou)

With very large `shared_buffers` settings, it was possible for the checkpoint to attempt to allocate more than 1GB for `fsync` requests, leading to failure and an infinite loop. Clamp the queue size to prevent this scenario.

- Avoid infinite wait in logical decoding when reading a partially-written WAL record (Vignesh C)

If the server crashes after writing the first part of a WAL record that would span multiple pages, subsequent logical decoding of the WAL stream would wait for data to arrive on the next WAL page. That might never happen if the server is now idle.

- Fix inconsistent quoting of role names in ACL strings (Tom Lane)

The previous quoting rule was locale-sensitive, which could lead to portability problems when transferring `aclitem` values across installations. (`pg_dump` does not do that, but other tools might.) To ensure consistency, always quote non-ASCII characters in `aclitem` output; but to preserve backward compatibility, never require that they be quoted during `aclitem` input.

- Reject equal signs (=) in the names of relation options and foreign-data options (Tom Lane)

There's no evident use-case for option names like this, and allowing them creates ambiguity in the stored representation.

- Avoid a rare scenario where a btree index scan could mark the wrong index entries as dead (Peter Geoghegan)
- Avoid re-distributing cache invalidation messages from other transactions during logical replication (vignesh C)

Our previous round of minor releases included a bug fix to ensure that replication receiver processes would respond to cross-process cache invalidation messages, preventing them from using stale catalog data while performing replication updates. However, the fix unintentionally made them also redistribute those messages again, leading to an exponential increase in the number of invalidation messages, which would often end in a memory allocation failure. Fix by not redistributing received messages.

- Avoid premature removal of old WAL during checkpoints (Vitaly Davydov)

If a replication slot's restart point is advanced while a checkpoint is in progress, no-longer-needed WAL segments could get removed too soon, leading to recovery failure if the database crashes immediately afterwards. Fix by keeping them for one additional checkpoint cycle.

- Never move a replication slot's confirmed-flush position backwards (Shveta Malik)

In some cases a replication client could acknowledge an LSN that's past what it has stored persistently, and then perhaps send an older LSN after a restart. We consider this not-a-bug so long as the client did not have anything it needed to do for the WAL between the two points. However, we should not re-send that WAL for fear of data duplication, so make sure we always believe the latest confirmed LSN for a given slot.

- Allow waiting for a transaction on a standby server to be interrupted (Kevin K Biju)

Creation of a replication slot on a standby server may require waiting for some active transaction(s) to finish on the primary and then be replayed on the standby. Since that could be an indefinite wait, it's desirable to allow the operation to be cancelled, but there was no check for query cancel in the loop.

- Fix some places that might try to fetch toasted fields of system catalogs without any snapshot (Nathan Bossart)

This could result in an assertion failure or “cannot fetch toast data without an active snapshot” error.

- Avoid assertion failure during cross-table constraint updates (Tom Lane, Jian He)
- Remove faulty assertion that a command tag must have been determined by the end of `PortalRunMulti()` (Álvaro Herrera)

This failed in edge cases such as an empty prepared statement.

- Restore the ability to run PL/pgSQL expressions in parallel (Dipesh Dhameliya)

PL/pgSQL's notion of an “expression” is very broad, encompassing any SQL `SELECT` query that returns a single column and no more than one row. So there are cases, for example evaluation of an aggregate function, where the query involves significant work and it'd be useful to run it with parallel workers. This used to be possible, but a previous bug fix unintentionally disabled it.

- Fix edge-case resource leaks in PL/Python error reporting (Tom Lane)

An out-of-memory failure while reporting an error from Python could result in failure to drop reference counts on Python objects, leading to session-lifespan memory leakage.

- Fix libpq's `PQport()` function to never return NULL unless the passed connection is NULL (Daniele Varrazzo)

This is the documented behavior, but recent libpq versions would return NULL in some cases where the user had not provided a port specification. Revert to our historical behavior of returning an empty string in such cases. (v18 and later will return the compiled-in default port number, typically "5432", instead.)

- Avoid failure when GSSAPI authentication requires packets larger than 16kB (Jacob Champion, Tom Lane)

Larger authentication packets are needed for Active Directory users who belong to many AD groups. This limitation manifested in connection failures with unintelligible error messages, typically "GSSAPI context establishment error: The routine must be called again to complete its function: Unknown error".

- Fix timing-dependent failures in SSL and GSSAPI data transmission (Tom Lane)

When using SSL or GSSAPI encryption in non-blocking mode, libpq sometimes failed with "SSL error: bad length" or "GSSAPI caller failed to retransmit all data needing to be retried".

- Avoid null-pointer dereference during connection lookup in ecpg applications (Aleksander Alekseev)

The case could occur only if the application has some connections that are named and some that are not.

- Improve psql's tab completion for `COPY` and `\copy` options (Atsushi Torikoshi)

The same completions were offered for both `COPY FROM` and `COPY TO`, although some options are only valid for one case or the other. Distinguish these cases to provide more accurate suggestions.

- Ensure that `pg_dump` dumps comments on domain constraints in a valid order (Jian He)

In some cases the comment command could appear before creation of the constraint.

- Ensure stable sort ordering in `pg_dump` for all types of database objects (Noah Misch, Andreas Karlsson)

`pg_dump` sorts objects by their logical names before performing dependency-driven reordering. This sort did not account for the full unique key identifying certain object types such as rules and constraints, and thus it could produce dissimilar sort orders for logically-identical databases. That made it difficult to compare databases by diff'ing `pg_dump` output, so improve the logic to ensure stable sort ordering in all cases.

- In `pg_upgrade`, check for inconsistent inherited not-null constraints (Ali Akbar)

PostgreSQL versions before 18 allow an inherited column not-null constraint to be dropped. However, this results in a schema that cannot be restored, leading to failure in `pg_upgrade`. Detect such cases during `pg_upgrade`'s preflight checks to allow users to fix them before initiating the upgrade.

- Avoid assertion failure if `track_commit_timestamp` is enabled during `initdb` (Hayato Kuroda, Andy Fan)
- Avoid possible leak of the open connection during `contrib/dblink` connection establishment (Tom Lane)

In the rare scenario where we hit out-of-memory while inserting the new connection object into `dblink`'s hashtable, the open connection would be leaked until end of session, leaving an idle session sitting on the remote server.

- Make `contrib/pg_prewarm` cope with very large `shared_buffers` settings (Daria Shanina)

Autoprewarm failed with a memory allocation error if `shared_buffers` was larger than about 50 million buffers (400GB).

- In `contrib/pg_stat_statements`, avoid leaving gaps in the set of parameter numbers used in a normalized query (Sami Imseih)

- Fix memory leakage in `contrib/postgres_fdw`'s `DirectModify` methods (Tom Lane)

The `PGresult` holding the results of the remote modify command would be leaked for the rest of the session if the query fails between invocations of the `DirectModify` methods, which could happen when there's `RETURNING` data to process.

- Ensure that directories listed in `configure`'s `--with-includes` and `--with-libraries` options are searched before system-supplied directories (Tom Lane)

A common reason for using these options is to allow a user-built version of some library to override the system-supplied version. However, that failed to work in some environments because of careless ordering of switches in the commands issued by the makefiles.

- Fix `configure`'s checks for `__cpuid()` and `__cpuidex()` (Lukas Fittl, Michael Paquier)

`configure` failed to detect these Windows-specific functions, so that they would not be used, leading to slower-than-necessary CRC computations since the availability of hardware instructions could not be verified. The practical impact of this error was limited, because production builds for Windows typically do not use the Autoconf toolchain.

- Fix build failure with `--with-pam` option on Solaris-based platforms (Tom Lane)

Solaris is inconsistent with other Unix platforms about the API for PAM authentication. This manifested as an “inconsistent pointer” compiler warning, which we never did anything about. But as of GCC 14 it's an error not warning by default, so fix it.

- Make our code portable to GNU Hurd (Michael Banck, Christoph Berg, Samuel Thibault)

Fix assumptions about `IOV_MAX` and `O_RDONLY` that don't hold on Hurd.

- Make our usage of `memset_s()` conform strictly to the C11 standard (Tom Lane)

This avoids compile failures on some platforms.

- Prevent uninitialized-value compiler warnings in JSONB comparison code (Tom Lane)
- Avoid deprecation warnings when building with libxml2 2.14 and later (Michael Paquier)
- Avoid problems when compiling `pg_locale.h` under C++ (John Naylor)

PostgreSQL header files generally need to be wrapped in `extern "C" { ... }` in order to be included in extensions written in C++. This failed for `pg_locale.h` because of its use of `libc` headers, but we can work around that by suppressing C++-only declarations in those headers. C++ extensions that want to use `libc`'s C++ APIs can do so by including the `libc` headers ahead of `pg_locale.h`.

## E.26. Release 14.18

**Release date:** 2025-05-08

This release contains a variety of fixes from 14.17. For information about new features in major release 14, see [Section E.44](#).

### E.26.1. Migration to Version 14.18

A dump/restore is not required for those running 14.X.

However, if you have any self-referential foreign key constraints on partitioned tables, it may be necessary to recreate those constraints to ensure that they are being enforced correctly. See the second changelog entry below.

Also, if you have any BRIN bloom indexes, it may be advisable to reindex them after updating. See the third changelog entry below.

Also, if you are upgrading from a version earlier than 14.14, see [Section E.30](#).

## E.26.2. Changes

- Avoid one-byte buffer overread when examining invalidly-encoded strings that are claimed to be in GB18030 encoding (Noah Misch, Andres Freund)

While unlikely, a SIGSEGV crash could occur if an incomplete multibyte character appeared at the end of memory. This was possible both in the server and in libpq-using applications. (CVE-2025-4207)

- Handle self-referential foreign keys on partitioned tables correctly (Álvaro Herrera)

Creating or attaching partitions failed to make the required catalog entries for a foreign-key constraint, if the table referenced by the constraint was the same partitioned table. This resulted in failure to enforce the constraint fully.

To fix this, you should drop and recreate any self-referential foreign keys on partitioned tables, if partitions have been created or attached since the constraint was created. Bear in mind that violating rows might already be present, in which case recreating the constraint will fail, and you'll need to fix up those rows before trying again.

- Avoid data loss when merging compressed BRIN summaries in `brin_bloom_union()` (Tomas Vondra)

The code failed to account for decompression results not being identical to the input objects, which would result in failure to add some of the data to the merged summary, leading to missed rows in index searches.

This mistake was present back to v14 where BRIN bloom indexes were introduced, but this code path was only rarely reached then. It's substantially more likely to be hit in v17 because parallel index builds now use the code.

- Fix unexpected “attribute has wrong type” errors in `UPDATE`, `DELETE`, and `MERGE` queries that use whole-row table references to views or functions in `FROM` (Tom Lane)
- Prevent failure in `INSERT` commands when the table has a `GENERATED` column of a domain data type and the domain's constraints disallow null values (Jian He)

Constraint failure was reported even if the generation expression produced a perfectly okay result.

- Correctly process references to outer CTE names that appear within a `WITH` clause attached to an `INSERT/UPDATE/DELETE/MERGE` command that's inside `WITH` (Tom Lane)

The parser failed to detect disallowed recursion cases, nor did it account for such references when sorting CTEs into a usable order.

- Fix `ARRAY(subquery)` and `ARRAY[expression, ...]` constructs to produce sane results when the input is of type `int2vector` or `oidvector` (Tom Lane)

This patch restores the behavior that existed before PostgreSQL 9.5: the result is of type `int2vector[]` or `oidvector[]`.

- Fix possible erroneous reports of invalid affixes while parsing Ispell dictionaries (Jacob Brazeal)
- Fix `ALTER TABLE ADD COLUMN` to correctly handle the case of a domain type that has a default (Jian He, Tom Lane, Tender Wang)

If a domain type has a default, adding a column of that type (without any explicit `DEFAULT` clause) failed to install the domain's default value in existing rows, instead leaving the new column null.

- Improve the error message for disallowed attempts to alter the properties of a foreign key constraint (Álvaro Herrera)
- Avoid error when resetting the `relhassubclass` flag of a temporary table that's marked `ON COMMIT DELETE ROWS` (Noah Misch)

- Fix planner's failure to identify more than one hashable `ScalarArrayOpExpr` subexpression within a top-level expression (David Geier)

This resulted in unnecessarily-inefficient execution of any additional subexpressions that could have been processed with a hash table (that is, `IN`, `NOT IN`, or `= ANY` clauses with all-constant right-hand sides).

- Disable “skip fetch” optimization in bitmap heap scan (Matthias van de Meent)

It turns out that this optimization can result in returning dead tuples when a concurrent vacuum marks a page all-visible.

- Fix performance issues in GIN index search startup when there are many search keys (Tom Lane, Vinod Sridharan)

An indexable clause with many keys (for example, `jsonbcol ?| array[...]` with tens of thousands of array elements) took  $O(N^2)$  time to start up, and was uncancelable for that interval too.

- Detect missing support procedures in a BRIN index operator class, and report an error instead of crashing (Álvaro Herrera)
- Respond to interrupts (such as query cancel) while waiting for asynchronous subplans of an Append plan node (Heikki Linnakangas)

Previously, nothing would happen until one of the subplans becomes ready.

- Fix race condition in handling of `synchronous_standby_names` immediately after startup (Melnikov Maksim, Michael Paquier)

For a short period after system startup, backends might fail to wait for synchronous commit even though `synchronous_standby_names` is enabled.

- Fix `pg_strerror()` to not crash with null `endptr` (Alexander Lakhin, Tom Lane)
- Avoid crash when a Snowball stemmer encounters an out-of-memory condition (Maksim Korotkov)
- Skip WAL recycling and preallocation during archive recovery, to avoid corruption of WAL files that were restored from the archive (Noah Misch, Arun Thirupathi)

This change back-patches v15-era fixes that were considered largely cosmetic at the time, but turn out to prevent data corruption in the wake of subsequent fixes.

- Prevent over-advancement of catalog xmin in “fast forward” mode of logical decoding (Zhijie Hou)

This mistake could allow deleted catalog entries to be vacuumed away even though they were still potentially needed by the WAL-reading process.

- Avoid data loss when DDL operations that don't take a strong lock affect tables that are being logically replicated (Shlok Kyal, Hayato Kuroda)

The catalog changes caused by the DDL command were not reflected into WAL-decoding processes, allowing them to decode subsequent changes using stale catalog data, probably resulting in data corruption.

- Avoid duplicate snapshot creation in logical replication index lookups (Heikki Linnakangas)
- Fix assertion failure in snapshot building (Masahiko Sawada)
- Fix overly-strict assertion in `gistFindCorrectParent()` (Heikki Linnakangas)
- Fix rare assertion failure in standby servers when the primary is restarted (Heikki Linnakangas)
- In PL/pgSQL, avoid “unexpected plan node type” error when a scrollable cursor is defined on a simple `SELECT expression` query (Andrei Lepikhov)
- Don't try to drop individual index partitions in `pg_dump`'s `--clean` mode (Jian He)

The server rejects such `DROP` commands. That has no real consequences, since the partitions will go away anyway in the subsequent `DROPS` of either their parent tables or their partitioned index.

However, the error reported for the attempted drop causes problems when restoring in `--single-transaction` mode.

- In `pg_dumpall`, avoid emitting invalid role `GRANT` commands if `pg_auth_members` contains invalid role OIDs (Tom Lane)

Instead, print a warning and skip the entry. This copes better with catalog corruption that has been seen to occur in back branches as a result of race conditions between `GRANT` and `DROP ROLE`.

- In `pg_amcheck` and `pg_upgrade`, use the correct function to free allocations made by `libpq` (Michael Paquier, Ranier Vilela)

These oversights could result in crashes in certain Windows build configurations, such as a debug build of `libpq` used by a non-debug build of the calling application.

- Allow `contrib/dblink` queries to be interrupted by query cancel (Noah Misch)

This change back-patches a v17-era fix. It prevents possible hangs in `CREATE DATABASE` and `DROP DATABASE` due to failure to detect deadlocks.

- Avoid crashing with corrupt input data in `contrib/pageinspect`'s `heap_page_items()` (Dmitry Kovalenko)
- Prevent assertion failure in `contrib/pg_freespacemap`'s `pg_freespacemap()` (Tender Wang)

Applying `pg_freespacemap()` to a relation lacking storage (such as a view) caused an assertion failure, although there was no ill effect in non-assert builds. Add an error check to reject that case.

- Fix build failure on macOS 15.4 (Tom Lane, Peter Eisentraut)

This macOS update broke our configuration probe for `strchrnul()`.

- Update time zone data files to tzdata release 2025b for DST law changes in Chile, plus historical corrections for Iran (Tom Lane)

There is a new time zone `America/Coyhaique` for Chile's Aysén Region, to account for it changing to UTC-03 year-round and thus diverging from `America/Santiago`.

## E.27. Release 14.17

**Release date:** 2025-02-20

This release contains a few fixes from 14.16. For information about new features in major release 14, see [Section E.44](#).

### E.27.1. Migration to Version 14.17

A dump/restore is not required for those running 14.X.

However, if you are upgrading from a version earlier than 14.14, see [Section E.30](#).

### E.27.2. Changes

- Improve behavior of `libpq`'s quoting functions (Andres Freund, Tom Lane)

The changes made for CVE-2025-1094 had one serious oversight: `PQescapeLiteral()` and `PQescapeIdentifier()` failed to honor their string length parameter, instead always reading to the input string's trailing null. This resulted in including unwanted text in the output, if the caller intended to truncate the string via the length parameter. With very bad luck it could cause a crash due to reading off the end of memory.

In addition, modify all these quoting functions so that when invalid encoding is detected, an invalid sequence is substituted for just the first byte of the presumed character, not all of it. This reduces the risk of problems if a calling application performs additional processing on the quoted string.

- Fix crash involving triggers on partitioned tables that make use of transition tables (Kyotaro Horiguchi)

If there are both `AFTER UPDATE` and `AFTER DELETE` triggers, the need for transition tables was determined incorrectly, leading to a crash during cross-partition updates.

## E.28. Release 14.16

**Release date:** 2025-02-13

This release contains a variety of fixes from 14.15. For information about new features in major release 14, see [Section E.44](#).

### E.28.1. Migration to Version 14.16

A dump/restore is not required for those running 14.X.

However, if you are upgrading from a version earlier than 14.14, see [Section E.30](#).

### E.28.2. Changes

- Harden `PQescapeString` and allied functions against invalidly-encoded input strings (Andres Freund, Noah Misch)

Data-quoting functions supplied by `libpq` now fully check the encoding validity of their input. If invalid characters are detected, they report an error if possible. For the ones that lack an error return convention, the output string is adjusted to ensure that the server will report invalid encoding and no intervening processing will be fooled by bytes that might happen to match single quote, backslash, etc.

The purpose of this change is to guard against SQL-injection attacks that are possible if one of these functions is used to quote crafted input. There is no hazard when the resulting string is sent directly to a PostgreSQL server (which would check its encoding anyway), but there is a risk when it is passed through `psql` or other client-side code. Historically such code has not carefully vetted encoding, and in many cases it's not clear what it should do if it did detect such a problem.

This fix is effective only if the data-quoting function, the server, and any intermediate processing agree on the character encoding that's being used. Applications that insert untrusted input into SQL commands should take special care to ensure that that's true.

Applications and drivers that quote untrusted input without using these `libpq` functions may be at risk of similar problems. They should first confirm the data is valid in the encoding expected by the server.

The PostgreSQL Project thanks Stephen Fewer for reporting this problem. (CVE-2025-1094)

- Exclude parallel workers from connection privilege checks and limits (Tom Lane)

Do not check `datallowconn`, `rolcanlogin`, and `ACL_CONNECT` privileges when starting a parallel worker, instead assuming that it's enough for the leader process to have passed similar checks originally. This avoids, for example, unexpected failures of parallelized queries when the leader is running as a role that lacks login privilege. In the same vein, enforce `ReservedConnections`, `datconnlimit`, and `rolconnlimit` limits only against regular backends, and count only regular backends while checking if the limits were already reached. Those limits are meant to prevent excessive consumption of process slots for regular backends --- but parallel workers and other special processes have their own pools of process slots with their own limit checks.

- Keep `TransactionXmin` in sync with `MyProc->xmin` (Heikki Linnakangas)

This oversight could permit a process to try to access data that had already been vacuumed away. One known consequence is transient “could not access status of transaction” errors.

- Fix race condition that could cause failure to add a newly-inserted catalog entry to a catalog cache list (Heikki Linnakangas)

This could result, for example, in failure to use a newly-created function within an existing session.

- Prevent possible catalog corruption when a system catalog is vacuumed concurrently with an update (Noah Misch)
- Fix data corruption when relation truncation fails (Thomas Munro)

The filesystem calls needed to perform relation truncation could fail, leaving inconsistent state on disk (for example, effectively reviving deleted data). We can't really prevent that, but we can recover by dint of making such failures into PANICs, so that consistency is restored by replaying from WAL up to just before the attempted truncation. This isn't a hugely desirable behavior, but such failures are rare enough that it seems an acceptable solution.

- Prevent checkpoints from starting during relation truncation (Robert Haas)

This avoids a race condition wherein the modified file might not get fsync'd before completing the checkpoint, creating a risk of data corruption if the operating system crashes soon after.

- Use `rename()` not `link()/unlink()` to rename files (Nathan Bossart)

The previous coding was intended to assure that the operation could not accidentally overwrite an existing file. However a failure could leave two links to the same file in existence, confusing subsequent operations and creating a risk of data corruption. In practice we do not use this functionality in places where the target filename could already exist, so it seems better to give up the no-overwrite guarantee to remove the multiple-link hazard.

- Avoid possibly losing an update of `pg_database.datfrozenxid` when `VACUUM` runs concurrently with a `REASSIGN OWNED` that changes that database's owner (Kirill Reshke)
- Fix incorrect `tg_updatedcols` values passed to `AFTER UPDATE` triggers (Tom Lane)

In some cases the `tg_updatedcols` bitmap could describe the set of columns updated by an earlier command in the same transaction, fooling the trigger into doing the wrong thing.

Also, prevent memory bloat caused by making too many copies of the `tg_updatedcols` bitmap.

- Fix mis-processing of `to_timestamp's` `FFn` format codes (Tom Lane)

An integer format code immediately preceding `FFn` would consume all available digits, leaving none for `FFn`.

- When deparsing an `XMLTABLE()` expression, ensure that XML namespace names are double-quoted when necessary (Dean Rasheed)
- Include the `ldapscheme` option in `pg_hba_file_rules()` output (Laurenz Albe)
- Don't merge `UNION` operations if their column collations aren't consistent (Tom Lane)

Previously we ignored collations when deciding if it's safe to merge `UNION` steps into a single N-way `UNION` operation. This was arguably valid before the introduction of nondeterministic collations, but it's not anymore, since the collation in use can affect the definition of uniqueness.

- Fix missed expression processing for partition pruning steps (Tom Lane)

This oversight could lead to “unrecognized node type” errors, and perhaps other problems, in queries accessing partitioned tables.

- Allow dshash tables to grow past 1GB (Matthias van de Meent)

This avoids errors like “invalid DSA memory alloc request size”. The case can occur for example in transactions that process several million tables.

- Avoid possible integer overflow in `bringetbitmap()` (James Hunter, Evgeniy Gorbanyov)

Since the result is only used for statistical purposes, the effects of this error were mostly cosmetic.

- Prevent streaming standby servers from looping infinitely when reading a WAL record that crosses pages (Kyotaro Horiguchi, Alexander Kukushkin)

This would happen when the record's continuation is on a page that needs to be read from a different WAL source.

- Improve performance of archiver process with many status files (Nathan Bossart)

This change back-patches a fix originally made in v15, in response to reports of extremely poor archiving performance leading to downtime or loss of replicas.

- Fix unintended promotion of FATAL errors to PANIC during early process startup (Noah Misch)

This fixes some unlikely cases that would result in “PANIC: proc\_exit() called in child process”.

- Fix cases where an operator family member operator or support procedure could become a dangling reference (Tom Lane)

In some cases a data type could be dropped while references to its OID still remain in `pg_amop` or `pg_amproc`. While that caused no immediate issues, an attempt to drop the owning operator family would fail, and `pg_dump` would produce bogus output when dumping the operator family. This fix causes creation and modification of operator families/classes to add needed dependency entries so that dropping a data type will also drop any dependent operator family elements. That does not help vulnerable pre-existing operator families, though, so a band-aid has also been added to `DROP OPERATOR FAMILY` to prevent failure when dropping a family that has dangling members.

- Fix multiple memory leaks in logical decoding output (Vignesh C, Masahiko Sawada, Boyu Yang)
- Avoid low-probability crash on out-of-memory, due to missing check for failure return from `malloc()` (Karina Litskevich)
- Avoid integer overflow while testing `wal_skip_threshold` condition (Tom Lane)

A transaction that created a very large relation could mistakenly decide to ensure durability by copying the relation into WAL instead of fsync'ing it, thereby negating the point of `wal_skip_threshold`. (This only matters when `wal_level` is set to `minimal`, else a WAL copy is required anyway.)

- Fix unsafe order of operations during cache lookups (Noah Misch)

The only known consequence was a usually-harmless “you don't own a lock of type ExclusiveLock” warning during `GRANT TABLESPACE`.

- Fix possible “failed to resolve name” failures when using JIT on older ARM platforms (Thomas Munro)

This could occur as a consequence of inconsistency about the default setting of `-moutline-atomics` between gcc and clang. At least Debian and Ubuntu are known to ship gcc and clang compilers that target armv8-a but differ on the use of outline atomics by default.

- Fix handling of Windows junction points that are not of PostgreSQL origin (Thomas Munro)

Previously, `initdb` would fail if the path to the data directory included junction points whose expansion isn't in “drive absolute” format, or whose expansion points to another junction point.

- Fix assertion failure in `WITH RECURSIVE ... UNION` queries (David Rowley)
- Avoid assertion failure in rule deparsing if a set operation leaf query contains set operations (Man Zeng, Tom Lane)
- Avoid edge-case assertion failure in parallel query startup (Tom Lane)
- In `NULLIF()`, avoid passing a read-write expanded object pointer to the data type's equality function (Tom Lane)

The equality function could modify or delete the object if it's given a read-write pointer, which would be bad if we decide to return it as the `NULLIF()` result. There is probably no problem with any built-in equality function, but it's easy to demonstrate a failure with one coded in PL/pgSQL.

- Ensure that expression preprocessing is applied to a default null value in `INSERT` (Tom Lane)

If the target column is of a domain type, the planner must insert a coerce-to-domain step not just a null constant, and this expression missed going through some required processing steps. There is no known consequence with domains based on core data types, but in theory an error could occur with domains based on extension types.

- Repair memory leaks in PL/Python (Mat Arye, Tom Lane)

Repeated use of `PLyPlan.execute` or `plpy.cursor` resulted in memory leakage for the duration of the calling PL/Python function.

- Fix PL/Tcl to compile with Tcl 9 (Peter Eisentraut)
- In the `ecpg` preprocessor, fix possible misprocessing of cursors that reference out-of-scope variables (Tom Lane)
- In `ecpg`, fix compile-time warnings about unsupported use of `COPY ... FROM STDIN` (Ryo Kanbayashi)

Previously, the intended warning was not issued due to a typo.

- Fix `psql` to safely handle file path names that are encoded in SJIS (Tom Lane)

Some two-byte characters in SJIS have a second byte that is equal to ASCII backslash (`\`). These characters were corrupted by path name normalization, preventing access to files whose names include such characters.

- Fix use of wrong version of `pqsignal()` in `pgbench` and `psql` (Fujii Masao, Tom Lane)

This error could lead to misbehavior when using the `-T` option in `pgbench` or the `\watch` command in `psql`, due to interrupted system calls not being resumed as expected.

- Fix misexecution of some nested `\if` constructs in `pgbench` (Michail Nikolaev)

An `\if` command appearing within a false (not-being-executed) `\if` branch was incorrectly treated the same as `\elif`.

- In `pgbench`, fix possible misdisplay of progress messages during table initialization (Yushi Ogiwara, Tatsuo Ishii, Fujii Masao)
- Make `pg_controldata` more robust against corrupted `pg_control` files (Ilyasov Ian, Anton Voloshin)

Since `pg_controldata` will attempt to print the contents of `pg_control` even if the CRC check fails, it must take care not to misbehave for invalid field values. This patch fixes some issues triggered by invalid timestamps and apparently-negative WAL segment sizes.

- Fix possible crash in `pg_dump` with identity sequences attached to tables that are extension members (Tom Lane)
- Fix `pg_basebackup` to correctly handle `pg_wal.tar` files exceeding 2GB on Windows (Davinder Singh, Thomas Munro)
- Update configuration probes that determine the compiler switches needed to access ARM CRC instructions (Tom Lane)

On ARM platforms where the baseline CPU target lacks CRC instructions, we need to supply a `-march` switch to persuade the compiler to compile such instructions. Recent versions of `gcc` reject the value we were trying, leading to silently falling back to software CRC.

- During configure, if a C23 compiler is detected, try asking for C17 (Thomas Munro)

PostgreSQL versions before v16 will not compile under C23 rules. If the chosen compiler defaults to C23 or later, try adding a `-std=gnu17` switch to change that. (If this won't work for your compiler, manually specify `CFLAGS` with a suitable switch.)

- Update time zone data files to tzdata release 2025a for DST law changes in Paraguay, plus historical corrections for the Philippines (Tom Lane)

## E.29. Release 14.15

**Release date:** 2024-11-21

This release contains a few fixes from 14.14. For information about new features in major release 14, see [Section E.44](#).

### E.29.1. Migration to Version 14.15

A dump/restore is not required for those running 14.X.

However, if you are upgrading from a version earlier than 14.14, see [Section E.30](#).

### E.29.2. Changes

- Repair ABI break for extensions that work with struct `ResultRelInfo` (Tom Lane)

Last week's minor releases unintentionally broke binary compatibility with `timescaledb` and several other extensions. Restore the affected structure to its previous size, so that such extensions need not be rebuilt.

- Restore functionality of `ALTER {ROLE|DATABASE} SET role` (Tom Lane, Noah Misch)

The fix for CVE-2024-10978 accidentally caused settings for `role` to not be applied if they come from non-interactive sources, including previous `ALTER {ROLE|DATABASE}` commands and the `PGOPTIONS` environment variable.

- Fix cases where a logical replication slot's `restart_lsn` could go backwards (Masahiko Sawada)

Previously, restarting logical replication could sometimes cause the slot's restart point to be recomputed as an older value than had previously been advertised in `pg_replication_slots`. This is bad, since for example WAL files might have been removed on the basis of the later `restart_lsn` value, in which case replication would fail to restart.

- Avoid deleting still-needed WAL files during `pg_rewrite` (Polina Bungina, Alexander Kukushkin)

Previously, in unlucky cases, it was possible for `pg_rewrite` to remove important WAL files from the rewound demoted primary. In particular this happens if those files have been marked for archival (i.e., their `.ready` files were created) but not yet archived. Then the newly promoted node no longer has such files because of them having been recycled, but likely they are needed for recovery in the demoted node. If `pg_rewrite` removes them, recovery is not possible anymore.

- Count index scans in `contrib/bloom` indexes in the statistics views, such as the `pg_stat_user_indexes.idx_scan` counter (Masahiro Ikeda)
- Fix crash when checking to see if an index's `opclass` options have changed (Alexander Korotkov)

Some forms of `ALTER TABLE` would fail if the table has an index with non-default operator class options.

- Avoid assertion failure caused by disconnected NFA sub-graphs in regular expression parsing (Tom Lane)

This bug does not appear to have any visible consequences in non-assert builds.

## E.30. Release 14.14

**Release date:** 2024-11-14

This release contains a variety of fixes from 14.13. For information about new features in major release 14, see [Section E.44](#).

### E.30.1. Migration to Version 14.14

A dump/restore is not required for those running 14.X.

However, if you have ever detached a partition from a partitioned table that has a foreign-key reference to another partitioned table, and not dropped the former partition, then you may have catalog and/or data corruption to repair, as detailed in the fifth changelog entry below.

Also, if you are upgrading from a version earlier than 14.12, see [Section E.32](#).

### E.30.2. Changes

- Ensure cached plans are marked as dependent on the calling role when RLS applies to a non-top-level table reference (Nathan Bossart)

If a CTE, subquery, sublink, security invoker view, or coercion projection in a query references a table with row-level security policies, we neglected to mark the resulting plan as potentially dependent on which role is executing it. This could lead to later query executions in the same session using the wrong plan, and then returning or hiding rows that should have been hidden or returned instead.

The PostgreSQL Project thanks Wolfgang Walther for reporting this problem. (CVE-2024-10976)

- Make libpq discard error messages received during SSL or GSS protocol negotiation (Jacob Champion)

An error message received before encryption negotiation is completed might have been injected by a man-in-the-middle, rather than being real server output. Reporting it opens the door to various security hazards; for example, the message might spoof a query result that a careless user could mistake for correct output. The best answer seems to be to discard such data and rely only on libpq's own report of the connection failure.

The PostgreSQL Project thanks Jacob Champion for reporting this problem. (CVE-2024-10977)

- Fix unintended interactions between `SET SESSION AUTHORIZATION` and `SET ROLE` (Tom Lane)

The SQL standard mandates that `SET SESSION AUTHORIZATION` have a side-effect of doing `SET ROLE NONE`. Our implementation of that was flawed, creating more interaction between the two settings than intended. Notably, rolling back a transaction that had done `SET SESSION AUTHORIZATION` would revert `ROLE` to `NONE` even if that had not been the previous state, so that the effective user ID might now be different from what it had been before the transaction. Transiently setting `session_authorization` in a function `SET` clause had a similar effect. A related bug was that if a parallel worker inspected `current_setting('role')`, it saw `none` even when it should see something else.

The PostgreSQL Project thanks Tom Lane for reporting this problem. (CVE-2024-10978)

- Prevent trusted PL/Perl code from changing environment variables (Andrew Dunstan, Noah Misch)

The ability to manipulate process environment variables such as `PATH` gives an attacker opportunities to execute arbitrary code. Therefore, “trusted” PLs must not offer the ability to do that. To fix `plperl`, replace `%ENV` with a tied hash that rejects any modification attempt with a warning. Untrusted `plperl` retains the ability to change the environment.

The PostgreSQL Project thanks Coby Abrams for reporting this problem. (CVE-2024-10979)

- Fix updates of catalog state for foreign-key constraints when attaching or detaching table partitions (Jehan-Guillaume de Rorthais, Tender Wang, Álvaro Herrera)

If the referenced table is partitioned, then different catalog entries are needed for a referencing table that is stand-alone versus one that is a partition. `ATTACH/DETACH PARTITION` commands failed to perform this conversion correctly. In particular, after `DETACH` the now stand-alone table would be missing foreign-key enforcement triggers, which could result in the table later containing rows that fail the foreign-key constraint. A subsequent `re-ATTACH` could fail with surprising errors, too.

The way to fix this is to do `ALTER TABLE DROP CONSTRAINT` on the now stand-alone table for each faulty constraint, and then re-add the constraint. If re-adding the constraint fails, then some erroneous data has crept in. You will need to manually re-establish consistency between the referencing and referenced tables, then re-add the constraint.

This query can be used to identify broken constraints and construct the commands needed to recreate them:

```
SELECT conrelid::pg_catalog.regclass AS "constrained table",
       conname AS constraint,
       confrelid::pg_catalog.regclass AS "references",
       pg_catalog.format('ALTER TABLE %s DROP CONSTRAINT %I;',
                          conrelid::pg_catalog.regclass, conname) AS "drop",
       pg_catalog.format('ALTER TABLE %s ADD CONSTRAINT %I %s;',
                          conrelid::pg_catalog.regclass, conname,
                          pg_catalog.pg_get_constraintdef(oid)) AS "add"
FROM pg_catalog.pg_constraint c
WHERE contype = 'f' AND conparentid = 0 AND
      ((SELECT count(*) FROM pg_catalog.pg_constraint c2
        WHERE c2.conparentid = c.oid) <>
      ((SELECT count(*) FROM pg_catalog.pg_inherits i
        WHERE (i.inhparent = c.conrelid OR i.inhparent = c.confrelid) AND
              EXISTS (SELECT 1 FROM pg_catalog.pg_partitioned_table
                      WHERE partrelid = i.inhparent)) +
      CASE WHEN pg_catalog.pg_partition_root(conrelid) = confrelid THEN
        (SELECT count(*) FROM pg_catalog.pg_partition_tree(confrelid)
         WHERE level = 1)
      ELSE 0 END);
```

Since it is possible that one or more of the `ADD CONSTRAINT` steps will fail, you should save the query's output in a file and then attempt to perform each step.

- Avoid possible crashes and “could not open relation” errors in queries on a partitioned table occurring concurrently with a `DETACH CONCURRENTLY` and immediate drop of a partition (Álvaro Herrera, Kuntal Gosh)
- Disallow `ALTER TABLE ATTACH PARTITION` if the table to be attached has a foreign key referencing the partitioned table (Álvaro Herrera)

This arrangement is not supported, and other ways of creating it already fail.

- Don't use partitionwise joins or grouping if the query's collation for the key column doesn't match the partition key's collation (Jian He, Webbo Han)

Such plans could produce incorrect results.

- Fix possible “could not find pathkey item to sort” error when the output of a `UNION ALL` member query needs to be sorted, and the sort column is an expression (Andrei Lepikhov, Tom Lane)
- Allow cancellation of the second stage of index build for large hash indexes (Pavel Borisov)
- Fix assertion failure or confusing error message for `COPY (query) TO ...`, when the `query` is rewritten by a `DO INSTEAD NOTIFY` rule (Tender Wang, Tom Lane)

- Fix detection of skewed data during parallel hash join (Thomas Munro)

After repartitioning the inner side of a hash join because one partition has accumulated too many tuples, we check to see if all the partition's tuples went into the same child partition, which suggests that they all have the same hash value and further repartitioning cannot improve matters. This check malfunctioned in some cases, allowing repeated futile repartitioning which would eventually end in a resource-exhaustion error.

- Fix race condition in committing a serializable transaction (Heikki Linnakangas)

Mis-processing of a recently committed transaction could lead to an assertion failure or a “could not access status of transaction” error.

- Fix race condition in `COMMIT PREPARED` that resulted in orphaned 2PC files (wuchengwen)

A concurrent `PREPARE TRANSACTION` could cause `COMMIT PREPARED` to not remove the on-disk two-phase state file for the completed transaction. There was no immediate ill effect, but a subsequent crash-and-recovery could fail with “could not access status of transaction”, requiring manual removal of the orphaned file to restore service.

- Avoid invalid memory accesses after skipping an invalid toast index during `VACUUM FULL` (Tender Wang)

A list tracking yet-to-be-rebuilt indexes was not properly updated in this code path, risking assertion failures or crashes later on.

- Fix ways in which an “in place” catalog update could be lost (Noah Misch)

Normal row updates write a new version of the row to preserve rollback-ability of the transaction. However, certain system catalog updates are intentionally non-transactional and are done with an in-place update of the row. These patches fix race conditions that could cause the effects of an in-place update to be lost. As an example, it was possible to forget having set `pg_class.relhasindex` to true, preventing updates of the new index and thus causing index corruption.

- Reset catalog caches at end of recovery (Noah Misch)

This prevents scenarios wherein an in-place catalog update could be lost due to using stale data from a catalog cache.

- Avoid using parallel query while holding off interrupts (Francesco Degrossi, Noah Misch, Tom Lane)

This situation cannot arise normally, but it can be reached with test scenarios such as using a SQL-language function as B-tree support (which would be far too slow for production usage). If it did occur it would result in an indefinite wait.

- Report the active query ID for statistics purposes at the start of processing of Bind and Execute protocol messages (Sami Imseih)

This allows more of the work done in extended query protocol to be attributed to the correct query.

- Guard against stack overflow in libxml2 with too-deeply-nested XML input (Tom Lane, with hat tip to Nick Wellnhofer)

Use `xmlXPathCtxtCompile()` rather than `xmlXPathCompile()`, because the latter fails to protect itself against recursion-to-stack-overflow in libxml2 releases before 2.13.4.

- Do not ignore a concurrent `REINDEX CONCURRENTLY` that is working on an index with predicates or expressions (Michail Nikolaev)

Normally, `REINDEX CONCURRENTLY` does not need to wait for other `REINDEX CONCURRENTLY` operations on other tables. However, this optimization is not applied if the other `REINDEX CONCURRENTLY` is processing an index with predicates or expressions, on the chance that such expressions contain user-defined code that accesses other tables. Careless coding created a race condition such that that rule was not applied uniformly, possibly allowing inconsistent behavior.

- Fix “failed to find plan for subquery/CTE” errors in `EXPLAIN` (Richard Guo, Tom Lane)

This case arose while trying to print references to fields of a `RECORD`-type output of a subquery when the subquery has been optimized out of the plan altogether (which is possible at least in the case that it has a constant-false `WHERE` condition). Nothing remains in the plan to identify the original field names, so fall back to printing `fN` for the *N*’th record column. (That’s actually the right thing anyway, if the record output arose from a `ROW()` constructor.)

- Disallow a `USING` clause when altering the type of a generated column (Peter Eisentraut)

A generated column already has an expression specifying the column contents, so including `USING` doesn’t make sense.

- Ignore not-yet-defined Portals in the `pg_cursors` view (Tom Lane)

It is possible for user-defined code that inspects this view to be called while a new cursor is being set up, and if that happens a null pointer dereference would ensue. Avoid the problem by defining the view to exclude incompletely-set-up cursors.

- Avoid “unexpected table\_index\_fetch\_tuple call during logical decoding” error while decoding a transaction involving insertion of a column default value (Takeshi Ideriha, Hou Zhijie)
- Reduce memory consumption of logical decoding (Masahiko Sawada)

Use a smaller default block size to store tuple data received during logical replication. This reduces memory wastage, which has been reported to be severe while processing long-running transactions, even leading to out-of-memory failures.

- Re-disable sending of stateless (TLSv1.2) session tickets (Daniel Gustafsson)

A previous change to prevent sending of stateful (TLSv1.3) session tickets accidentally re-enabled sending of stateless ones. Thus, while we intended to prevent clients from thinking that TLS session resumption is supported, some still did.

- Avoid “wrong tuple length” failure when dropping a database with many ACL (permission) entries (Ayush Tiwari)
- Allow adjusting the `session_authorization` and `role` settings in parallel workers (Tom Lane)

Our code intends to allow modifiable server settings to be set by function `SET` clauses, but not otherwise within a parallel worker. `SET` clauses failed for these two settings, though.

- Fix behavior of stable functions called from a `CALL` statement’s argument list, when the `CALL` is within a PL/pgSQL `EXCEPTION` block (Tom Lane)

As with a similar fix in our previous quarterly releases, this case allowed such functions to be passed the wrong snapshot, causing them to see stale values of rows modified since the start of the outer transaction.

- Fix “cache lookup failed for function” errors in edge cases in PL/pgSQL’s `CALL` (Tom Lane)
- Fix thread safety of our fallback (non-OpenSSL) MD5 implementation on big-endian hardware (Heikki Linnakangas)

Thread safety is not currently a concern in the server, but it is for libpq.

- Parse libpq’s `keepalives` connection option in the same way as other integer-valued options (Yuto Sasaki)

The coding used here rejected trailing whitespace in the option value, unlike other cases. This turns out to be problematic in `ecpg`’s usage, for example.

- Avoid use of `pnstrdup()` in `ecpglib` (Jacob Champion)

That function will call `exit()` on out-of-memory, which is undesirable in a library. The calling code already handles allocation failures properly.

- In `ecpglib`, fix out-of-bounds read when parsing incorrect datetime input (Bruce Momjian, Pavel Nekrasov)

It was possible to try to read the location just before the start of a constant array. Real-world consequences seem minimal, though.

- Include the source timeline history in `pg_rewind`'s debug output (Heikki Linnakangas)

This was the intention to begin with, but a coding error caused the source history to always print as empty.

- Fix misbehavior with junction points on Windows, particularly in `pg_rewind` (Alexandra Wang)

This entailed back-patching previous fixes by Thomas Munro, Peter Eisentraut, Alexander Lakhin, and Juan José Santamaría Flecha. Those changes were originally not back-patched out of caution, but they have been in use in later branches for long enough to deem them safe.

- Avoid trying to reindex temporary tables and indexes in `vacuumdb` and in `parallel reindexdb` (VaibhaveS, Michael Paquier, Fujii Masao, Nathan Bossart)

Reindexing other sessions' temporary tables cannot work, but the check to skip them was missing in some code paths, leading to unwanted failures.

- Allow inspection of sequence relations in relevant functions of `contrib/pageinspect` and `contrib/pgstattuple` (Nathan Bossart, Ayush Vatsa)

This had been allowed in the past, but it got broken during the introduction of non-default access methods for tables.

- Fix incorrect LLVM-generated code on ARM64 platforms (Thomas Munro, Anthonin Bonnefoy)

When using JIT compilation on ARM platforms, the generated code could not support relocation distances exceeding 32 bits, allowing unlucky placement of generated code to cause server crashes on large-memory systems.

- Fix a few places that assumed that process start time (represented as a `time_t`) will fit into a `long` value (Max Johnson, Nathan Bossart)

On platforms where `long` is 32 bits (notably Windows), this coding would fail after Y2038. Most of the failures appear only cosmetic, but notably `pg_ctl start` would hang.

- Prevent “nothing provides perl(PostgreSQL::Test::Utils)” failures while building RPM packages of PostgreSQL (Noah Misch)
- Fix building with Strawberry Perl on Windows (Andrew Dunstan)
- Update time zone data files to tzdata release 2024b (Tom Lane)

This tzdata release changes the old System-V-compatibility zone names to duplicate the corresponding geographic zones; for example `PST8PDT` is now an alias for `America/Los_Angeles`. The main visible consequence is that for timestamps before the introduction of standardized time zones, the zone is considered to represent local mean solar time for the named location. For example, in `PST8PDT`, `timestampz` input such as `1801-01-01 00:00` would previously have been rendered as `1801-01-01 00:00:00-08`, but now it is rendered as `1801-01-01 00:00:00-07:52:58`.

Also, historical corrections for Mexico, Mongolia, and Portugal. Notably, `Asia/Choibalsan` is now an alias for `Asia/Ulaanbaatar` rather than being a separate zone, mainly because the differences between those zones were found to be based on untrustworthy data.

## E.31. Release 14.13

**Release date:** 2024-08-08

This release contains a variety of fixes from 14.12. For information about new features in major release 14, see [Section E.44](#).

### E.31.1. Migration to Version 14.13

A dump/restore is not required for those running 14.X.

However, if you are upgrading from a version earlier than 14.12, see [Section E.32](#).

### E.31.2. Changes

- Prevent unauthorized code execution during `pg_dump` (Masahiko Sawada)

An attacker able to create and drop non-temporary objects could inject SQL code that would be executed by a concurrent `pg_dump` session with the privileges of the role running `pg_dump` (which is often a superuser). The attack involves replacing a sequence or similar object with a view or foreign table that will execute malicious code. To prevent this, introduce a new server parameter `restrict_nonsystem_relation_kind` that can disable expansion of non-builtin views as well as access to foreign tables, and teach `pg_dump` to set it when available. Note that the attack is prevented only if both `pg_dump` and the server it is dumping from are new enough to have this fix.

The PostgreSQL Project thanks Noah Misch for reporting this problem. (CVE-2024-7348)

- Prevent infinite loop in `VACUUM` (Melanie Plageman)

After a disconnected standby server with an old running transaction reconnected to the primary, it was possible for `VACUUM` on the primary to get confused about which tuples are removable, resulting in an infinite loop.

- Fix failure after attaching a table as a partition, if the table had previously had inheritance children (Álvaro Herrera)
- Fix `ALTER TABLE DETACH PARTITION` for cases involving inconsistent index-based constraints (Álvaro Herrera, Tender Wang)

When a partitioned table has an index that is not associated with a constraint, but a partition has an equivalent index that is, then detaching the partition would misbehave, leaving the ex-partition's constraint with an incorrect `coninhcount` value. This would cause trouble during any further manipulations of that constraint.

- Fix partition pruning setup during `ALTER TABLE DETACH PARTITION CONCURRENTLY` (Álvaro Herrera)

The executor assumed that no partition could be detached between planning and execution of a query on a partitioned table. This is no longer true since the introduction of `DETACH PARTITION's CONCURRENTLY` option, making it possible for query execution to fail transiently when that is used.

- Correctly update a partitioned table's `pg_class.reltuples` field to zero after its last child partition is dropped (Noah Misch)

The first `ANALYZE` on such a partitioned table must update `relhassubclass` as well, and that caused the `reltuples` update to be lost.

- Fix handling of polymorphic output arguments for procedures (Tom Lane)

The SQL `CALL` statement did not resolve the correct data types for such arguments, leading to errors such as “cannot display a value of type anyelement”, or even outright crashes. (But `CALL` in PL/pgSQL worked correctly.)

- Fix behavior of stable functions called from a `CALL` statement's argument list (Tom Lane)

If the `CALL` is within an atomic context (e.g. there's an outer transaction block), such functions were passed the wrong snapshot, causing them to see stale values of rows modified since the start of the outer transaction.

- Detect integer overflow in `money` calculations (Joseph Koschakow)

None of the arithmetic functions for the `money` type checked for overflow before, so they would silently give wrong answers for overflowing cases.

- Fix over-aggressive clamping of the scale argument in `round(numeric)` and `trunc(numeric)` (Dean Rasheed)

These functions clamped their scale argument to  $\pm 2000$ , but there are valid use-cases for it to be larger; the functions returned incorrect results in such cases. Instead clamp to the actual allowed range of type `numeric`.

- Prevent `pg_sequence_last_value()` from failing on unlogged sequences on standby servers and on temporary sequences of other sessions (Nathan Bossart)

Make it return NULL in these cases instead of throwing an error.

- Fix parsing of ignored operators in `websearch_to_tsquery()` (Tom Lane)

Per the manual, punctuation in the input of `websearch_to_tsquery()` is ignored except for the special cases of dashes and quotes. However, parentheses and a few other characters appearing immediately before an `or` could cause `or` to be treated as a data word, rather than as an `OR` operator as expected.

- Detect another integer overflow case while computing new array dimensions (Joseph Koshakow)

Reject applying array dimensions `[-2147483648:2147483647]` to an empty array. This is closely related to CVE-2023-5869, but appears harmless since the array still ends up empty.

- Detect another case of a new catalog cache entry becoming stale while detoasting its fields (Noah Misch)

An in-place update occurring while we expand out-of-line fields in a catalog tuple could be missed, leading to a catalog cache entry that lacks the in-place change but is not known to be stale. This is only possible in the `pg_database` catalog, so the effects are narrow, but misbehavior is possible.

- Correctly check updatability of view columns targeted by `INSERT ... DEFAULT` (Tom Lane)

If such a column is non-updatable, we should give an error reporting that. But the check was missed and then later code would report an unhelpful error such as “attribute number *N* not found in view targetlist”.

- Avoid reporting an unhelpful internal error for incorrect recursive queries (Tom Lane)

Rearrange the order of error checks so that we throw an on-point error when a `WITH RECURSIVE` query does not have a self-reference within the second arm of the `UNION`, but does have one self-reference in some other place such as `ORDER BY`.

- Don't throw an error if a queued `AFTER` trigger no longer exists (Tom Lane)

It's possible for a transaction to execute an operation that queues a deferred `AFTER` trigger for later execution, and then to drop the trigger before that happens. Formerly this led to weird errors such as “could not find trigger *NNNN*”. It seems better to silently do nothing if the trigger no longer exists at the time when it would have been executed.

- Fix failure to remove `pg_init_privs` entries for column-level privileges when their table is dropped (Tom Lane)

If an extension grants some column-level privileges on a table it creates, relevant catalog entries would remain behind after the extension is dropped. This was harmless until/unless the table's OID was re-used for another relation, when it could interfere with what `pg_dump` dumps for that relation.

- Fix selection of an arbiter index for `ON CONFLICT` when the desired index has expressions or predicates (Tom Lane)

If a query using `ON CONFLICT` accesses the target table through an updatable view, it could fail with “there is no unique or exclusion constraint matching the `ON CONFLICT` specification”, even though a matching index does exist.

- Refuse to modify a temporary table of another session with `ALTER TABLE` (Tom Lane)

Permissions checks normally would prevent this case from arising, but it is possible to reach it by altering a parent table whose child is another session's temporary table. Throw an error if we discover that such a child table belongs to another session.

- Fix handling of extended statistics on expressions in `CREATE TABLE LIKE STATISTICS` (Tom Lane)

The `CREATE` command failed to adjust column references in statistics expressions to the possibly-different column numbering of the new table. This resulted in invalid statistics objects that would cause problems later. A typical scenario where renumbering columns is needed is when the source table contains some dropped columns.

- Fix failure to recalculate sub-queries generated from `MIN()` or `MAX()` aggregates (Tom Lane)

In some cases the aggregate result computed at one row of the outer query could be re-used for later rows when it should not be. This has only been seen to happen when the outer query uses `DISTINCT` that is implemented with hash aggregation, but other cases may exist.

- Avoid crashing when a JIT-inlined backend function throws an error (Tom Lane)

The error state can include pointers into the dynamically loaded module holding the JIT-compiled code (for error location strings). In some code paths the module could get unloaded before the error report is processed, leading to `SIGSEGV` when the location strings are accessed.

- Cope with behavioral changes in libxml2 version 2.13.x (Erik Wienhold, Tom Lane)

Notably, we now suppress “chunk is not well balanced” errors from libxml2, unless that is the only reported error. This is to make error reports consistent between 2.13.x and earlier libxml2 versions. In earlier versions, that message was almost always redundant or outright incorrect, so 2.13.x substantially reduced the number of cases in which it's reported.

- Fix handling of subtransactions of prepared transactions when starting a hot standby server (Heikki Linnakangas)

When starting a standby's replay at a shutdown checkpoint WAL record, transactions that had been prepared but not yet committed on the primary are correctly understood as being still in progress. But subtransactions of a prepared transaction (created by savepoints or PL/pgSQL exception blocks) were not accounted for and would be treated as aborted. That led to inconsistency if the prepared transaction was later committed.

- Prevent incorrect initialization of logical replication slots (Masahiko Sawada)

In some cases a replication slot's start point within the WAL stream could be set to a point within a transaction, leading to assertion failures or incorrect decoding results.

- Avoid memory leakage after servicing a notify or `sinval` interrupt (Tom Lane)

The processing functions for these events could switch the current memory context to `TopMemoryContext`, resulting in session-lifespan leakage of any data allocated before the incorrect setting gets replaced. There were observable leaks associated with (at least) encoding conversion of incoming queries and parameters attached to `Bind` messages.

- Prevent deadlocks and assertion failures during truncation of the multixact SLRU log (Heikki Linnakangas)

A process trying to delete SLRU segments could deadlock with the checkpoint process.

- Avoid possibly missing end-of-input events on Windows sockets (Thomas Munro)

Windows reports an `FD_CLOSE` event only once after the remote end of the connection disconnects. With unlucky timing, we could miss that report and wait indefinitely, or at least until a timeout elapsed, expecting more input.

- Fix buffer overread in JSON parse error reports for incomplete byte sequences (Jacob Champion)

It was possible to walk off the end of the input buffer by a few bytes when the last bytes comprise an incomplete multi-byte character. While usually harmless, in principle this could cause a crash.

- Disable creation of stateful TLS session tickets by OpenSSL (Daniel Gustafsson)

This avoids possible failures with clients that think receipt of a session ticket means that TLS session resumption is supported.

- When replanning a PL/pgSQL “simple expression”, check it's still simple (Tom Lane)

Certain fairly-artificial cases, such as dropping a referenced function and recreating it as an aggregate, could lead to surprising failures such as “unexpected plan node type”.

- Fix incompatibility between PL/Perl and Perl 5.40 (Andrew Dunstan)
- Fix recursive `RECORD`-returning PL/Python functions (Tom Lane)

If we recurse to a new call of the same function that passes a different column definition list (`AS` clause), it would fail because the inner call would overwrite the outer call's idea of what rowtype to return.

- Don't corrupt PL/Python's `TD` dictionary during a recursive trigger call (Tom Lane)

If a PL/Python-language trigger caused another one to be invoked, the `TD` dictionary created for the inner one would overwrite the outer one's `TD` dictionary.

- Fix PL/Tcl's reporting of invalid list syntax in the result of a function returning tuple (Erik Wienhold, Tom Lane)

Such a case could result in a crash, or in emission of misleading context information that actually refers to the previous Tcl error.

- Avoid non-thread-safe usage of `strerror()` in `libpq` (Peter Eisentraut)

Certain error messages returned by OpenSSL could become garbled in multi-threaded applications.

- Ensure that `pg_restore -l` reports dependent TOC entries correctly (Tom Lane)

If `-l` was specified together with selective-restore options such as `-n` or `-N`, dependent TOC entries such as comments would be omitted from the listing, even when an actual restore would have selected them.

- In `contrib/postgres_fdw`, do not send `FETCH FIRST WITH TIES` clauses to the remote server (Japin Li)

The remote server might not implement this clause, or might interpret it differently than we would locally, so don't risk attempting remote execution.

- Avoid clashing with system-provided `<regex.h>` headers (Thomas Munro)

This fixes a compilation failure on macOS version 15 and up.

- Fix otherwise-harmless assertion failure in Memoize cost estimation (David Rowley)
- Fix otherwise-harmless assertion failures in `REINDEX CONCURRENTLY` applied to an SP-GiST index (Tom Lane)

## E.32. Release 14.12

**Release date:** 2024-05-09

This release contains a variety of fixes from 14.11. For information about new features in major release 14, see [Section E.44](#).

### E.32.1. Migration to Version 14.12

A dump/restore is not required for those running 14.X.

However, a security vulnerability was found in the system views `pg_stats_ext` and `pg_stats_ext_exprs`, potentially allowing authenticated database users to see data they shouldn't. If this is of concern in your installation, follow the steps in the first changelog entry below to rectify it.

Also, if you are upgrading from a version earlier than 14.11, see [Section E.33](#).

### E.32.2. Changes

- Restrict visibility of `pg_stats_ext` and `pg_stats_ext_exprs` entries to the table owner (Nathan Bossart)

These views failed to hide statistics for expressions that involve columns the accessing user does not have permission to read. View columns such as `most_common_vals` might expose security-relevant data. The potential interactions here are not fully clear, so in the interest of erring on the side of safety, make rows in these views visible only to the owner of the associated table.

The PostgreSQL Project thanks Lukas Fittl for reporting this problem. (CVE-2024-4317)

By itself, this fix will only fix the behavior in newly initdb'd database clusters. If you wish to apply this change in an existing cluster, you will need to do the following:

1. Find the SQL script `fix-CVE-2024-4317.sql` in the `share` directory of the PostgreSQL installation (typically located someplace like `/usr/share/postgresql/`). Be sure to use the script appropriate to your PostgreSQL major version. If you do not see this file, either your version is not vulnerable (only v14-v16 are affected) or your minor version is too old to have the fix.

2. In *each* database of the cluster, run the `fix-CVE-2024-4317.sql` script as superuser. In `psql` this would look like

```
\i /usr/share/postgresql/fix-CVE-2024-4317.sql
```

(adjust the file path as appropriate). Any error probably indicates that you've used the wrong script version. It will not hurt to run the script more than once.

3. Do not forget to include the `template0` and `template1` databases, or the vulnerability will still exist in databases you create later. To fix `template0`, you'll need to temporarily make it accept connections. Do that with

```
ALTER DATABASE template0 WITH ALLOW_CONNECTIONS true;
```

and then after fixing `template0`, undo it with

```
ALTER DATABASE template0 WITH ALLOW_CONNECTIONS false;
```

- Fix `INSERT` from multiple `VALUES` rows into a target column that is a domain over an array or composite type (Tom Lane)

Such cases would either fail with surprising complaints about mismatched datatypes, or insert unexpected coercions that could lead to odd results.

- Fix incorrect pruning of `NULL` partition when a table is partitioned on a boolean column and the query has a boolean `IS NOT` clause (David Rowley)

A `NULL` value satisfies a clause such as `boolcol IS NOT FALSE`, so pruning away a partition containing `NULL`s yielded incorrect answers.

- Make `ALTER FOREIGN TABLE SET SCHEMA` move any owned sequences into the new schema (Tom Lane)

Moving a regular table to a new schema causes any sequences owned by the table to be moved to that schema too (along with indexes and constraints). This was overlooked for foreign tables, however.

- Improve `ALTER TABLE ... ALTER COLUMN TYPE`'s error message when there is a dependent function or publication (Tom Lane)
- Fix `EXPLAIN`'s counting of heap pages accessed by a bitmap heap scan (Melanie Plageman)

Previously, heap pages that contain no visible tuples were not counted; but it seems more consistent to count all pages returned by the bitmap index scan.

- Avoid deadlock during removal of orphaned temporary tables (Mikhail Zhilin)

If the session that creates a temporary table crashes without removing the table, autovacuum will eventually try to remove the orphaned table. However, an incoming session that's been assigned the same temporary namespace will do that too. If a temporary table has a dependency (such as an owned sequence) then a deadlock could result between these two cleanup attempts.

- Avoid race condition while examining per-relation frozen-XID values (Noah Misch)

`VACUUM`'s computation of per-database frozen-XID values from per-relation values could get confused by a concurrent update of those values by another `VACUUM`.

- Disallow converting a table to a view within an outer SQL command that is using that table (Tom Lane)

This avoids possible crashes.

- Ensure that join conditions generated from equivalence classes are applied at the correct plan level (Tom Lane)

In versions before PostgreSQL 16, it was possible for generated conditions to be evaluated below outer joins when they should be evaluated above (after) the outer join, leading to incorrect query results. All versions have a similar hazard when considering joins to `UNION ALL` trees that have constant outputs for the join column in some `SELECT` arms.

- Avoid unnecessary use of moving-aggregate mode with a non-moving window frame (Vallimaharajan G)

When a plain aggregate is used as a window function, and the window frame start is specified as `UNBOUNDED PRECEDING`, the frame's head cannot move so we do not need to use the special (and more expensive) moving-aggregate mode. This optimization was intended all along, but due to a coding error it never triggered.

- Avoid use of already-freed data while planning partition-wise joins under GEQO (Tom Lane)

This would typically end in a crash or unexpected error message.

- Avoid freeing still-in-use data in Memoize (Tender Wang, Andrei Lepikhov)

In production builds this error frequently didn't cause any problems, as the freed data would most likely not get overwritten before it was used.

- Fix incorrectly-reported statistics kind codes in "requested statistics kind *x* is not yet built" error messages (David Rowley)
- Be more careful with `RECORD`-returning functions in `FROM` (Tom Lane)

The output columns of such a function call must be defined by an `AS` clause that specifies the column names and data types. If the actual function output value doesn't match that, an error is supposed to be thrown at runtime. However, some code paths would examine the actual value prematurely, and potentially issue strange errors or suffer assertion failures if it doesn't match expectations.

- Fix confusion about the return rowtype of SQL-language procedures (Tom Lane)

A procedure implemented in SQL language that returns a single composite-type column would cause an assertion failure or core dump.

- Add protective stack depth checks to some recursive functions (Egor Chindyaskin)
- Fix mis-rounding and overflow hazards in `date_bin()` (Moaaz Assali)

In the case where the source timestamp is before the origin timestamp and their difference is already an exact multiple of the stride, the code incorrectly subtracted the stride anyway. Also, detect some integer-overflow cases that would have produced incorrect results.

- Detect integer overflow when adding or subtracting an `interval` to/from a `timestamp` (Joseph Koshakow)

Some cases that should cause an out-of-range error produced an incorrect result instead.

- Avoid race condition in `pg_get_expr()` (Tom Lane)

If the relation referenced by the argument is dropped concurrently, the function's intention is to return NULL, but sometimes it failed instead.

- Fix detection of old transaction IDs in XID status functions (Karina Litskevich)

Transaction IDs more than  $2^{31}$  transactions in the past could be misidentified as recent, leading to misbehavior of `pg_xact_status()` or `txid_status()`.

- Ensure that a table's freespace map won't return a page that's past the end of the table (Ronan Dunklau)

Because the freespace map isn't WAL-logged, this was possible in edge cases involving an OS crash, a replica promote, or a PITR restore. The result would be a “could not read block” error.

- Fix file descriptor leakage when an error is thrown while waiting in `WaitEventSetWait` (Etsuro Fujita)
- Avoid corrupting exception stack if an FDW implements `async append` but doesn't configure any wait conditions for the `Append` plan node to wait for (Alexander Pyhalov)
- Throw an error if an index is accessed while it is being reindexed (Tom Lane)

Previously this was just an assertion check, but promote it into a regular runtime error. This will provide a more on-point error message when reindexing a user-defined index expression that attempts to access its own table.

- Ensure that index-only scans on `name` columns return a fully-padded value (David Rowley)

The value physically stored in the index is truncated, and previously a pointer to that value was returned to callers. This provoked complaints when testing under `valgrind`. In theory it could result in crashes, though none have been reported.

- Fix crash with DSM allocations larger than 4GB (Heikki Linnakangas)
- Disconnect if a new server session's client socket cannot be put into non-blocking mode (Heikki Linnakangas)

It was once theoretically possible for us to operate with a socket that's in blocking mode; but that hasn't worked fully in a long time, so fail at connection start rather than misbehave later.

- Fix inadequate error reporting with OpenSSL 3.0.0 and later (Heikki Linnakangas, Tom Lane)

System-reported errors passed through by OpenSSL were reported with a numeric error code rather than anything readable.

- Avoid concurrent calls to `bindtextdomain()` in `libpq` and `ecpglib` (Tom Lane)

Although GNU gettext's implementation seems to be fine with concurrent calls, the version available on Windows is not.

- Fix crash in `ecpg`'s preprocessor if the program tries to redefine a macro that was defined on the preprocessor command line (Tom Lane)
- In `ecpg`, avoid issuing false “unsupported feature will be passed to server” warnings (Tom Lane)
- Ensure that the string result of `ecpg`'s `intoasc()` function is correctly zero-terminated (Oleg Tselbrovskiy)
- Fix `pg_dumpall` so that role comments, if present, will be dumped regardless of the setting of `--no-role-passwords` (Daniel Gustafsson, Álvaro Herrera)
- Fix PL/pgSQL's parsing of single-line comments (`---`-style comments) following expressions (Erik Wienhold, Tom Lane)

This mistake caused parse errors if such a comment followed a `WHEN` expression in a PL/pgSQL `CASE` statement.

- In `contrib/amcheck`, don't report false match failures due to short- versus long-header values (Andrey Borodin, Michael Zhilin)

A variable-length datum in a heap tuple or index tuple could have either a short or a long header, depending on compression parameters that applied when it was made. Treat these cases as equivalent rather than complaining if there's a difference.

- Fix bugs in BRIN output functions (Tomas Vondra)

These output functions are only used for displaying index entries in `contrib/pageinspect`, so the errors are of limited practical concern.

- In `contrib/postgres_fdw`, avoid emitting requests to sort by a constant (David Rowley)

This could occur in cases involving `UNION ALL` with constant-emitting subqueries. Sorting by a constant is useless of course, but it also risks being misinterpreted by the remote server, leading to “ORDER BY position *N* is not in select list” errors.

- Make `contrib/postgres_fdw` set the remote session's time zone to `GMT` not `UTC` (Tom Lane)

This should have the same results for practical purposes. However, `GMT` is recognized by hard-wired code in the server, while `UTC` is looked up in the timezone database. So the old code could fail in the unlikely event that the remote server's timezone database is missing entries.

- In `contrib/xml2`, avoid use of library functions that have been deprecated in recent versions of `libxml2` (Dmitry Koval)
- Fix incompatibility with LLVM 18 (Thomas Munro, Dmitry Dolgov)
- Allow `make check` to work with the musl C library (Thomas Munro, Bruce Momjian, Tom Lane)

## E.33. Release 14.11

**Release date:** 2024-02-08

This release contains a variety of fixes from 14.10. For information about new features in major release 14, see [Section E.44](#).

### E.33.1. Migration to Version 14.11

A dump/restore is not required for those running 14.X.

However, one bug was fixed that could have resulted in corruption of GIN indexes during concurrent updates. If you suspect such corruption, reindex affected indexes after installing this update.

Also, if you are upgrading from a version earlier than 14.10, see [Section E.34](#).

### E.33.2. Changes

- Tighten security restrictions within `REFRESH MATERIALIZED VIEW CONCURRENTLY` (Heikki Linnakangas)

One step of a concurrent refresh command was run under weak security restrictions. If a materialized view's owner could persuade a superuser or other high-privileged user to perform a concurrent refresh on that view, the view's owner could control code executed with the privileges of the user running `REFRESH`. Fix things so that all user-determined code is run as the view's owner, as expected.

The only known exploit for this error does not work in PostgreSQL 16.0 and later, so it may be that v16 is not vulnerable in practice.

The PostgreSQL Project thanks Pedro Gallegos for reporting this problem. (CVE-2024-0985)

- Fix memory leak when performing JIT inlining (Andres Freund, Daniel Gustafsson)

There have been multiple reports of backend processes suffering out-of-memory conditions after sufficiently many JIT compilations. This fix should resolve that.

- When dequeuing from an LWLock, avoid needing to search the list of waiting processes (Andres Freund)

This fixes  $O(N^2)$  behavior when the list of waiters is long. In some use-cases this results in substantial throughput improvements.

- Avoid generating incorrect partitioned-join plans (Richard Guo)

Some uncommon situations involving lateral references could create incorrect plans. Affected queries could produce wrong answers, or odd failures such as “variable not found in subplan target list”, or executor crashes.

- Fix incorrect wrapping of subquery output expressions in PlaceholderVars (Tom Lane)

This fixes incorrect results when a subquery is underneath an outer join and has an output column that laterally references something outside the outer join's scope. The output column might not appear as NULL when it should do so due to the action of the outer join.

- Prevent access to a no-longer-pinned buffer in `BEFORE ROW UPDATE` triggers (Alexander Lakhin, Tom Lane)

If the tuple being updated had just been updated and moved to another page by another session, there was a narrow window where we would attempt to fetch data from the new tuple version without any pin on its buffer. In principle this could result in garbage data appearing in non-updated columns of the proposed new tuple. The odds of problems in practice seem rather low, however.

- Avoid requesting an oversize shared-memory area in parallel hash join (Thomas Munro, Andrei Lepikhov, Alexander Korotkov)

The limiting value was too large, allowing “invalid DSA memory alloc request size” errors to occur with sufficiently large expected hash table sizes.

- Avoid assertion failures in `heap_update()` and `heap_delete()` when a tuple to be updated by a foreign-key enforcement trigger fails the extra visibility crosscheck (Alexander Lakhin)

This error had no impact in non-assert builds.

- Fix overly tight assertion about `false_positive_rate` parameter of BRIN bloom operator classes (Alexander Lakhin)

This error had no impact in non-assert builds, either.

- Fix possible failure during `ALTER TABLE ADD COLUMN` on a complex inheritance tree (Tender Wang)

If a grandchild table would inherit the new column via multiple intermediate parents, the command failed with “tuple already updated by self”.

- Fix problems with duplicate token names in `ALTER TEXT SEARCH CONFIGURATION ... MAPPING` commands (Tender Wang, Michael Paquier)
- Properly lock the associated table during `DROP STATISTICS` (Tomas Vondra)

Failure to acquire the lock could result in “tuple concurrently deleted” errors if the `DROP` executes concurrently with `ANALYZE`.

- Fix function volatility checking for `GENERATED` and `DEFAULT` expressions (Tom Lane)

These places could fail to detect insertion of a volatile function default-argument expression, or decide that a polymorphic function is volatile although it is actually immutable on the datatype of interest. This could lead to improperly rejecting or accepting a `GENERATED` clause, or to mistakenly applying the constant-default-value optimization in `ALTER TABLE ADD COLUMN`.

- Detect that a new catalog cache entry became stale while detoasting its fields (Tom Lane)

We expand any out-of-line fields in a catalog tuple before inserting it into the catalog caches. That involves database access which might cause invalidation of catalog cache entries — but the new entry isn't in the cache yet, so we would miss noticing that it should get invalidated. The result is a race condition in which an already-stale cache entry could get made, and then persist indefinitely. This would lead to hard-to-predict misbehavior. Fix by rechecking the tuple's visibility after detoasting.

- Fix edge-case integer overflow detection bug on some platforms (Dean Rasheed)

Computing `0 - INT64_MIN` should result in an overflow error, and did on most platforms. However, platforms with neither integer overflow builtins nor 128-bit integers would fail to spot the overflow, instead returning `INT64_MIN`.

- Detect Julian-date overflow when adding or subtracting an `interval` to/from a `timestamp` (Tom Lane)

Some cases that should cause an out-of-range error produced an incorrect result instead.

- Add more checks for overflow in `interval_mul()` and `interval_div()` (Dean Rasheed)

Some cases that should cause an out-of-range error produced an incorrect result instead.

- Make the `pg_file_settings` view check validity of unapplied values for settings with `backend` or `superuser-backend` context (Tom Lane)

Invalid values were not noted in the view as intended. This escaped detection because there are very few settings in these groups.

- Match collation too when matching an existing index to a new partitioned index (Peter Eisentraut)

Previously we could accept an index that has a different collation from the corresponding element of the partition key, possibly leading to misbehavior.

- Avoid failure if a child index is dropped concurrently with `REINDEX INDEX` on a partitioned index (Fei Changhong)
- Fix insufficient locking when cleaning up an incomplete split of a GIN index's internal page (Fei Changhong, Heikki Linnakangas)

The code tried to do this with shared rather than exclusive lock on the buffer. This could lead to index corruption if two processes attempted the cleanup concurrently.

- Avoid premature release of buffer pin in GIN index insertion (Tom Lane)

If an index root page split occurs concurrently with our own insertion, the code could fail with “buffer NNNN is not owned by resource owner”.

- Avoid failure with partitioned SP-GiST indexes (Tom Lane)

Trying to use an index of this kind could lead to “No such file or directory” errors.

- Fix ownership change reporting for large objects (Tom Lane)

A no-op `ALTER LARGE OBJECT OWNER` command (that is, one selecting the existing owner) passed the wrong class ID to the `PostAlterHook`, probably confusing any extension using that hook.

- Prevent standby servers from incorrectly processing dead index tuples during subtransactions (Fei Changhong)

The `startedInRecovery` flag was not correctly set for a subtransaction. This affects only processing of dead index tuples. It could allow a query in a subtransaction to ignore index entries that it should return (if they are already dead on the primary server, but not dead to the standby transaction), or to prematurely mark index entries as dead that are not yet dead on the primary. It is not clear that the latter case has any serious consequences, but it's not the intended behavior.

- Fix deadlock between a logical replication apply worker, its `tablesync` worker, and a session process trying to alter the subscription (Shlok Kyal)

One edge of the deadlock loop did not involve a lock wait, so the deadlock went undetected and would persist until manual intervention.

- Prevent examining system catalogs with the wrong snapshot during logical decoding (Fei Changhong)

If decoding begins partway through a transaction that modifies system catalogs, the decoder may not recognize that, causing it to fail to treat that transaction as in-progress for catalog lookups. This fix deals with the case that a top-level transaction is already marked as containing catalog changes, but its subtransaction(s) are not.

- Return the correct status code when a new client disconnects without responding to the server's password challenge (Liu Lang, Tom Lane)

In some cases we'd treat this as a loggable error, which was not the intention and tends to create log spam, since common clients like `psql` frequently do this. It may also confuse extensions that use `ClientAuthentication_hook`.

- Fix incompatibility with OpenSSL 3.2 (Tristan Partin, Bo Andreson)

Use the `BIO “app_data”` field for our private storage, instead of assuming it's okay to use the “data” field. This mistake didn't cause problems before, but with 3.2 it leads to crashes and complaints about double frees.

- Be more wary about OpenSSL not setting `errno` on error (Tom Lane)

If `errno` isn't set, assume the cause of the reported failure is read EOF. This fixes rare cases of strange error reports like “could not accept SSL connection: Success”.

- Fix file descriptor leakage when a foreign data wrapper's `ForeignAsyncRequest` function fails (Heikki Linnakangas)
- Report ENOMEM errors from file-related system calls as `ERRCODE_OUT_OF_MEMORY`, not `ERRCODE_INTERNAL_ERROR` (Alexander Kuzmenkov)
- In PL/pgSQL, support SQL commands that are `CREATE FUNCTION/CREATE PROCEDURE` with SQL-standard bodies (Tom Lane)

Previously, such cases failed with parsing errors due to the semicolon(s) appearing in the function body.

- Fix libpq's handling of errors in pipelines (Álvaro Herrera)

The pipeline state could get out of sync if an error is returned for reasons other than a query problem (for example, if the connection is lost). Potentially this would lead to a busy-loop in the calling application.

- Make libpq's `PQsendFlushRequest()` function flush the client output buffer under the same rules as other `PQsend` functions (Jelte Fennema-Nio)

In pipeline mode, it may still be necessary to call `PQflush()` as well; but this change removes some inconsistency.

- Avoid race condition when libpq initializes OpenSSL support concurrently in two different threads (Willi Mann, Michael Paquier)
- Fix timing-dependent failure in GSSAPI data transmission (Tom Lane)

When using GSSAPI encryption in non-blocking mode, libpq sometimes failed with “GSSAPI caller failed to retransmit all data needing to be retried”.

- In `pg_dump`, don't dump RLS policies or security labels for extension member objects (Tom Lane, Jacob Champion)

Previously, commands would be included in the dump to set these properties, which is really incorrect since they should be considered as internal affairs of the extension. Moreover, the restoring user might not have adequate privilege to set them, and indeed the dumping user might not have enough privilege to dump them (since dumping RLS policies requires acquiring lock on their table).

- In `pg_dump`, don't dump an extended statistics object if its underlying table isn't being dumped (Rian McGuire, Tom Lane)

This conforms to the behavior for other dependent objects such as indexes.

- Make it an error for a `pgbench` script to end with an open pipeline (Anthonin Bonnefoy)

Previously, `pgbench` would behave oddly if a `\startpipeline` command lacked a matching `\endpipeline`. This seems like a scripting mistake rather than a case that `pgbench` needs to handle nicely, so throw an error.

- Fix crash in `contrib/intarray` if an array with an element equal to `INT_MAX` is inserted into a `gist__int_ops` index (Alexander Lakhin, Tom Lane)
- Report a better error when `contrib/pageinspect`'s `hash_bitmap_info()` function is applied to a partitioned hash index (Alexander Lakhin, Michael Paquier)
- Report a better error when `contrib/pgstattuple`'s `pgstathashindex()` function is applied to a partitioned hash index (Alexander Lakhin)
- On Windows, suppress autorun options when launching subprocesses in `pg_ctl` and `pg_regress` (Kyotaro Horiguchi)

When launching a child process via `cmd.exe`, pass the `/D` flag to prevent executing any autorun commands specified in the registry. This avoids possibly-surprising side effects.

- Fix compilation failures with libxml2 version 2.12.0 and later (Tom Lane)
- Fix compilation failure of `WAL_DEBUG` code on Windows (Bharath Rupireddy)
- Suppress compiler warnings from Python's header files (Peter Eisentraut, Tom Lane)

Our preferred compiler options provoke warnings about constructs appearing in recent versions of Python's header files. When using `gcc`, we can suppress these warnings with a `pragma`.

- Avoid deprecation warning when compiling with LLVM 18 (Thomas Munro)
- Update time zone data files to `tzdata` release 2024a for DST law changes in Greenland, Kazakhstan, and Palestine, plus corrections for the Antarctic stations Casey and Vostok. Also historical corrections for Vietnam, Toronto, and Miquelon. (Tom Lane)

## E.34. Release 14.10

**Release date:** 2023-11-09

This release contains a variety of fixes from 14.9. For information about new features in major release 14, see [Section E.44](#).

### E.34.1. Migration to Version 14.10

A dump/restore is not required for those running 14.X.

However, several mistakes have been discovered that could lead to certain types of indexes yielding wrong search results or being unnecessarily inefficient. It is advisable to `REINDEX` potentially-affected indexes after installing this update. See the fourth through seventh changelog entries below.

Also, if you are upgrading from a version earlier than 14.9, see [Section E.35](#).

### E.34.2. Changes

- Fix handling of unknown-type arguments in `DISTINCT "any"` aggregate functions (Tom Lane)

This error led to a `text`-type value being interpreted as an `unknown`-type value (that is, a zero-terminated string) at runtime. This could result in disclosure of server memory following the `text` value.

The PostgreSQL Project thanks Jingzhou Fu for reporting this problem. (CVE-2023-5868)

- Detect integer overflow while computing new array dimensions (Tom Lane)

When assigning new elements to array subscripts that are outside the current array bounds, an undetected integer overflow could occur in edge cases. Memory stomps that are potentially exploitable for arbitrary code execution are possible, and so is disclosure of server memory.

The PostgreSQL Project thanks Pedro Gallegos for reporting this problem. (CVE-2023-5869)

- Prevent the `pg_signal_backend` role from signalling background workers and autovacuum processes (Noah Misch, Jelte Fennema-Nio)

The documentation says that `pg_signal_backend` cannot issue signals to superuser-owned processes. It was able to signal these background processes, though, because they advertise a role OID of zero. Treat that as indicating superuser ownership. The security implications of cancelling one of these process types are fairly small so far as the core code goes (we'll just start another one), but extensions might add background workers that are more vulnerable.

Also ensure that the `is_superuser` parameter is set correctly in such processes. No specific security consequences are known for that oversight, but it might be significant for some extensions.

The PostgreSQL Project thanks Hemanth Sandrana and Mahendrakar Srinivasarao for reporting this problem. (CVE-2023-5870)

- Fix misbehavior during recursive page split in GiST index build (Heikki Linnakangas)

Fix a case where the location of a page downlink was incorrectly tracked, and introduce some logic to allow recovering from such situations rather than silently doing the wrong thing. This error could result in incorrect answers from subsequent index searches. It may be advisable to `reindex` all GiST indexes after installing this update.

- Prevent de-duplication of btree index entries for `interval` columns (Noah Misch)

There are `interval` values that are distinguishable but compare equal, for example `24:00:00` and `1 day`. This breaks assumptions made by btree de-duplication, so `interval` columns need to be excluded from de-duplication. This oversight can cause incorrect results from index-only scans. Moreover, after updating `amcheck` will report an error for almost all such indexes. Users should `reindex` any btree indexes on `interval` columns.

- Process `date` values more sanely in BRIN `datetime_minmax_multi_ops` indexes (Tomas Vondra)

The distance calculation for dates was backward, causing poor decisions about which entries to merge. The index still produces correct results, but is much less efficient than it should be. Reindexing BRIN `minmax_multi` indexes on `date` columns is advisable.

- Process large `timestamp` and `timestampz` values more sanely in BRIN `datetime_minmax_multi_ops` indexes (Tomas Vondra)

Infinites were mistakenly treated as having distance zero rather than a large distance from other values, causing poor decisions about which entries to merge. Also, finite-but-very-large values (near the endpoints of the representable timestamp range) could result in internal overflows, again causing poor decisions. The index still produces correct results, but is much less efficient than it should be. Reindexing BRIN `minmax_multi` indexes on `timestamp` and `timestampz` columns is advisable if the column contains, or has contained, infinities or large finite values.

- Avoid calculation overflows in BRIN `interval_minmax_multi_ops` indexes with extreme interval values (Tomas Vondra)

This bug might have caused unexpected failures while trying to insert large interval values into such an index.

- Fix partition step generation and runtime partition pruning for hash-partitioned tables with multiple partition keys (David Rowley)

Some cases involving an `IS NULL` condition on one of the partition keys could result in a crash.

- Correctly identify the target table in an inherited `UPDATE/DELETE/MERGE` even when the parent table is excluded by constraints (Amit Langote, Tom Lane)

If the initially-named table is excluded by constraints, but not all its inheritance descendants are, the first non-excluded descendant was identified as the primary target table. This would lead to firing statement-level triggers associated with that table, rather than the initially-named table as should happen. In v16, the same oversight could also lead to “invalid perminfoindex 0 in RTE with relid NNNN” errors.

- Fix edge case in btree mark/restore processing of `ScalarArrayOpExpr` clauses (Peter Geoghegan)

When restoring an indexscan to a previously marked position, the code could miss required set-up steps if the scan had advanced exactly to the end of the matches for a `ScalarArrayOpExpr` (that is, an `indexcol = ANY(ARRAY[])`) clause. This could result in missing some rows that should have been fetched.

- Fix intra-query memory leak in Memoize execution (Orlov Aleksej, David Rowley)
- Fix intra-query memory leak when a set-returning function repeatedly returns zero rows (Tom Lane)
- Don't crash if `cursor_to_xmlschema()` is applied to a non-data-returning Portal (Boyu Yang)
- Throw the intended error if `pgrowlocks()` is applied to a partitioned table (David Rowley)

Previously, a not-on-point complaint “only heap AM is supported” would be raised.

- Handle invalid indexes more cleanly in assorted SQL functions (Noah Misch)

Report an error if `pgstatindex()`, `pgstatginindex()`, `pgstathashindex()`, or `pgstattuple()` is applied to an invalid index. If `brin_desummarize_range()`, `brin_summarize_new_values()`, `brin_summarize_range()`, or `gin_clean_pending_list()` is applied to an invalid index, do nothing except to report a debug-level message. Formerly these functions attempted to process the index, and might fail in strange ways depending on what the failed `CREATE INDEX` had left behind.

- Avoid premature memory allocation failure with long inputs to `to_tsvector()` (Tom Lane)
- Fix over-allocation of the constructed `tsvector` in `tsvectorrecv()` (Denis Erokhin)

If the incoming vector includes position data, the binary receive function left wasted space (roughly equal to the size of the position data) in the finished `tsvector`. In extreme cases this could lead to “maximum total lexeme length exceeded” failures for vectors that were under the length limit when emitted. In any case it could lead to wasted space on-disk.

- Fix incorrect coding in `gtsvector_picksplit()` (Alexander Lakhin)

This could lead to poor page-split decisions in GiST indexes on `tsvector` columns.

- Improve checks for corrupt PGLZ compressed data (Flavien Guedez)
- Fix `COMMIT AND CHAIN/ROLLBACK AND CHAIN` to work properly when there is an unreleased save-point (Liu Xiang, Tom Lane)

Instead of propagating the current transaction's properties to the new transaction, they propagated some previous transaction's properties.

- In `COPY FROM`, fail cleanly when an unsupported encoding conversion is needed (Tom Lane)

Recent refactoring accidentally removed the intended error check for this, such that it ended in “cache lookup failed for function 0” instead of a useful error message.

- Avoid crash in `EXPLAIN` if a parameter marked to be displayed by `EXPLAIN` has a NULL boot-time value (Xing Guo, Aleksander Alekseev, Tom Lane)

No built-in parameter fits this description, but an extension could define such a parameter.

- Ensure we have a snapshot while dropping `ON COMMIT DROP` temp tables (Tom Lane)

This prevents possible misbehavior if any catalog entries for the temp tables have fields wide enough to require toasting (such as a very complex `CHECK` condition).

- Avoid improper response to shutdown signals in child processes just forked by `system()` (Nathan Bossart)

This fix avoids a race condition in which a child process that has been forked off by `system()`, but hasn't yet exec'd the intended child program, might receive and act on a signal intended for the parent server process. That would lead to duplicate cleanup actions being performed, which will not end well.

- Cope with torn reads of `pg_control` in frontend programs (Thomas Munro)

On some file systems, reading `pg_control` may not be an atomic action when the server concurrently writes that file. This is detectable via a bad CRC. Retry a few times to see if the file becomes valid before we report error.

- Avoid torn reads of `pg_control` in relevant SQL functions (Thomas Munro)

Acquire the appropriate lock before reading `pg_control`, to ensure we get a consistent view of that file.

- Avoid integer overflow when computing size of backend activity string array (Jakub Wartak)

On 64-bit machines we will allow values of `track_activity_query_size` large enough to cause 32-bit overflow when multiplied by the allowed number of connections. The code actually allocating the per-backend local array was careless about this though, and allocated the array incorrectly.

- Fix briefly showing inconsistent progress statistics for `ANALYZE` on inherited tables (Heikki Lin-nakangas)

The block-level counters should be reset to zero at the same time we update the current-relation field.

- Fix the background writer to report any WAL writes it makes to the statistics counters (Nazir Bilal Yavuz)

- Track the dependencies of cached `CALL` statements, and re-plan them when needed (Tom Lane)

DDL commands, such as replacement of a function that has been inlined into a `CALL` argument, can create the need to re-plan a `CALL` that has been cached by PL/pgSQL. That was not happening, leading to misbehavior or strange errors such as “cache lookup failed”.

- Track nesting depth correctly when inspecting `RECORD`-type Vars from outer query levels (Richard Guo)

This oversight could lead to assertion failures, core dumps, or “bogus varno” errors.

- Track hash function and negator function dependencies of `ScalarArrayOpExpr` plan nodes (David Rowley)

In most cases this oversight was harmless, since these functions would be unlikely to disappear while the node's original operator remains present.

- Fix error-handling bug in `RECORD` type cache management (Thomas Munro)

An out-of-memory error occurring at just the wrong point could leave behind inconsistent state that would lead to an infinite loop.

- Fix assertion failure when logical decoding is retried in the same session after an error (Hou Zhijie)
- Treat out-of-memory failures as fatal while reading WAL (Michael Paquier)

Previously this would be treated as a bogus-data condition, leading to the conclusion that we'd reached the end of WAL, which is incorrect and could lead to inconsistent WAL replay.

- Fix possible recovery failure due to trying to allocate memory based on a bogus WAL record length field (Thomas Munro, Michael Paquier)
- Ensure that standby-mode WAL recovery reports an error when an invalid page header is found (Yugo Nagata, Kyotaro Horiguchi)
- Fix datatype size confusion in logical tape management (Ranier Vilela)

Integer overflow was possible on platforms where long is wider than int, although it would take a multiple-terabyte temporary file to cause a problem.

- Avoid unintended close of sysloger process's stdin (Heikki Linnakangas)
- Avoid doing plan cache revalidation of utility statements that do not receive interesting processing during parse analysis (Tom Lane)

Aside from saving a few cycles, this prevents failure after a cache invalidation for statements that must not set a snapshot, such as `SET TRANSACTION ISOLATION LEVEL`.

- Keep by-reference `attmissingval` values in a long-lived context while they are being used (Andrew Dunstan)

This avoids possible use of dangling pointers when a tuple slot outlives the tuple descriptor with which its value was constructed.

- Recalculate the effective value of `search_path` after `ALTER ROLE` (Jeff Davis)

This ensures that after renaming a role, the meaning of the special string `$user` is re-determined.

- Fix “could not duplicate handle” error occurring on Windows when `min_dynamic_shared_memory` is set above zero (Thomas Munro)
- Fix order of operations in `GenericXLogFinish` (Jeff Davis)

This code violated the conditions required for crash safety by writing WAL before marking changed buffers dirty. No core code uses this function, but extensions do (`contrib/bloom` does, for example).

- Remove incorrect assertion in PL/Python exception handling (Alexander Lakhin)
- Fix `pg_restore` so that selective restores will include both table-level and column-level ACLs for selected tables (Euler Taveira, Tom Lane)

Formerly, only the table-level ACL would get restored if both types were present.

- Add logic to `pg_upgrade` to check for use of `abstime`, `reltime`, and `tinterval` data types (Álvaro Herrera)

These obsolete data types were removed in PostgreSQL version 12, so check to make sure they aren't present in an older database before claiming it can be upgraded.

- Avoid generating invalid temporary slot names in `pg_basebackup` (Jelte Fennema)

This has only been seen to occur when the server connection runs through `pgbouncer`.

- Avoid false “too many client connections” errors in `pgbench` on Windows (Noah Misch)
- In `contrib/amcheck`, do not report interrupted page deletion as corruption (Noah Misch)

This fix prevents false-positive reports of “the first child of leftmost target page is not leftmost of its level”, “block NNNN is not leftmost” or “left link/right link pair in index XXXX not in agreement”. They appeared if `amcheck` ran after an unfinished `btree` index page deletion and before `VACUUM` had cleaned things up.

- Fix failure of `contrib/btree_gin` indexes on interval columns, when an `indexscan` using the `<` or `<=` operator is performed (Dean Rasheed)

Such an `indexscan` failed to return all the entries it should.

- Add support for LLVM 16 and 17 (Thomas Munro, Dmitry Dolgov)
- Suppress assorted build-time warnings on recent macOS (Tom Lane)

Xcode 15 (released with macOS Sonoma) changed the linker's behavior in a way that causes many duplicate-library warnings while building PostgreSQL. These were harmless, but they're annoying so avoid citing the same libraries twice. Also remove use of the `-multiply_defined suppress` linker switch, which apparently has been a no-op for a long time, and is now actively complained of.

- When building `contrib/unaccent`'s rules file, fall back to using `python` if `--with-python` was not given and make variable `PYTHON` was not set (Japin Li)
- Remove `PHOT` (Phoenix Islands Time) from the default timezone abbreviations list (Tom Lane)

Presence of this abbreviation in the default list can cause failures on recent Debian and Ubuntu releases, as they no longer install the underlying `tzdb` entry by default. Since this is a made-up abbreviation for a zone with a total human population of about two dozen, it seems unlikely that anyone will miss it. If someone does, they can put it back via a custom abbreviations file.

## E.35. Release 14.9

**Release date:** 2023-08-10

This release contains a variety of fixes from 14.8. For information about new features in major release 14, see [Section E.44](#).

### E.35.1. Migration to Version 14.9

A dump/restore is not required for those running 14.X.

However, if you use BRIN indexes, it may be advisable to reindex them; see the second changelog entry below.

Also, if you are upgrading from a version earlier than 14.4, see [Section E.40](#).

## E.35.2. Changes

- Disallow substituting a schema or owner name into an extension script if the name contains a quote, backslash, or dollar sign (Noah Misch)

This restriction guards against SQL-injection hazards for trusted extensions.

The PostgreSQL Project thanks Micah Gates, Valerie Woolard, Tim Carey-Smith, and Christoph Berg for reporting this problem. (CVE-2023-39417)

- Fix confusion between empty (no rows) ranges and all-NULL ranges in BRIN indexes, as well as incorrect merging of all-NULL summaries (Tomas Vondra)

Each of these oversights could result in forgetting that a BRIN index range contains any NULL values, potentially allowing subsequent queries that should return NULL values to miss doing so.

This fix will not in itself correct faulty BRIN entries. It's recommended to `REINDEX` any BRIN indexes that may be used to search for nulls.

- Avoid leaving a corrupted database behind when `DROP DATABASE` is interrupted (Andres Freund)

If `DROP DATABASE` was interrupted after it had already begun taking irreversible steps, the target database remained accessible (because the removal of its `pg_database` row would roll back), but it would have corrupt contents. Fix by marking the database as inaccessible before we begin to perform irreversible operations. A failure after that will leave the database still partially present, but nothing can be done with it except to issue another `DROP DATABASE`.

- Ensure that partitioned indexes are correctly marked as valid or not at creation (Michael Paquier)

If a new partitioned index matches an existing but invalid index on one of the partitions, the partitioned index could end up being marked valid prematurely. This could lead to misbehavior or assertion failures in subsequent queries on the partitioned table.

- Ignore invalid child indexes when matching partitioned indexes to child indexes during `ALTER TABLE ATTACH PARTITION` (Michael Paquier)

Such an index will now be ignored, and a new child index created instead.

- Fix possible failure when marking a partitioned index valid after all of its partitions have been attached (Michael Paquier)

The update of the index's `pg_index` entry could use stale data for other columns. One reported symptom is an “attempted to update invisible tuple” error.

- Fix `ALTER EXTENSION SET SCHEMA` to complain if the extension contains any objects outside the extension's schema (Michael Paquier, Heikki Linnakangas)

Erroring out if the extension contains objects in multiple schemas was always intended; but the check was mis-coded so that it would fail to detect some cases, leading to surprising behavior.

- Don't use partial unique indexes for uniqueness proofs in the planner (David Rowley)

This could give rise to incorrect plans, since the presumed uniqueness of rows read from a table might not hold if the index in question isn't used to scan the table.

- Don't Memoize lateral joins with volatile join conditions (Richard Guo)

Applying Memoize to a sub-plan that contains volatile filter conditions is likely to lead to wrong answers. The check to avoid doing this missed some cases that can arise when using `LATERAL`.

- Avoid producing incorrect plans for foreign joins with pseudoconstant join clauses (Etsuro Fujita)

The planner currently lacks support for attaching pseudoconstant join clauses to a pushed-down remote join, so disable generation of remote joins in such cases. (A better solution will require ABI-breaking changes of planner data structures, so it will have to wait for a future major release.)

- Correctly handle sub-SELECTs in RLS policy expressions and security-barrier views when expanding rule actions (Tom Lane)
- Fix race conditions in conflict detection for `SERIALIZABLE` isolation mode (Thomas Munro)

Conflicts could be missed when using bitmap heap scans, when using GIN indexes, and when examining an initially-empty btree index. All these cases could lead to serializability failures due to improperly allowing conflicting transactions to commit.

- Fix misbehavior of `EvalPlanQual` checks with inherited or partitioned target tables (Tom Lane)

This oversight could lead to update or delete actions in `READ COMMITTED` isolation mode getting performed when they should have been skipped because of a conflicting concurrent update.

- Fix hash join with an inner-side hash key that contains Params coming from an outer nested loop (Tom Lane)

When rescanning the join after the values of such Params have changed, we must rebuild the hash table, but neglected to do so. This could result in missing join output rows.

- Fix intermittent failures when trying to update a field of a composite column (Tom Lane)

If the overall value of the composite column is wide enough to require out-of-line toasting, then an unluckily-timed cache flush could cause errors or server crashes.

- Prevent query-lifespan memory leaks in some `UPDATE` queries with triggers (Tomas Vondra)
- Prevent query-lifespan memory leaks when an Incremental Sort plan node is rescanned (James Coleman, Laurenz Albe, Tom Lane)
- Accept fractional seconds in the input to `jsonpath's datetime()` method (Tom Lane)
- Prevent stack-overflow crashes with very complex text search patterns (Tom Lane)
- Allow tokens up to 10240 bytes long in `pg_hba.conf` and `pg_ident.conf` (Tom Lane)

The previous limit of 256 bytes has been found insufficient for some use-cases.

- Fix mishandling of C++ out-of-memory conditions (Heikki Linnakangas)

If JIT is in use, running out of memory in a C++ `new` call would lead to a PostgreSQL FATAL error, instead of the expected C++ exception.

- Fix rare null-pointer crash in `plancache.c` (Tom Lane)
- Avoid losing track of possibly-useful shared memory segments when a page free results in coalescing ranges of free space (Dongming Liu)

Ensure that the segment is moved into the appropriate “bin” for its new amount of free space, so that it will be found by subsequent searches.

- Allow `VACUUM` to continue after detecting certain types of b-tree index corruption (Peter Geoghegan)

If an invalid sibling-page link is detected, log the issue and press on, rather than throwing an error as before. Nothing short of `REINDEX` will fix the broken index, but preventing `VACUUM` from completing until that is done risks making matters far worse.

- Ensure that `WrapLimitsVacuumLock` is released after `VACUUM` detects invalid data in `pg_data-base.datfrozenxid` or `pg_database.datminmxid` (Andres Freund)

Failure to release this lock could lead to a deadlock later, although the lock would be cleaned up if the session exits or encounters some other error.

- Avoid double replay of prepared transactions during crash recovery (suyu.cmj, Michael Paquier)

After a crash partway through a checkpoint with some two-phase transaction state data already flushed to disk by this checkpoint, crash recovery could attempt to replay the prepared transaction(s) twice, leading to a fatal error such as “lock is already held” in the startup process.

- Fix possible failure while promoting a standby server, if archiving is enabled and two-phase transactions need to be recovered (Julian Markwort)

If any required two-phase transactions were logged in the most recent (partial) log segment, promotion would fail with an incorrect complaint about “requested WAL segment has already been removed”.

- Ensure that a newly created, but still empty table is `fsync`'ed at the next checkpoint (Heikki Linnakangas)

Without this, if there is an operating system crash causing the empty file to disappear, subsequent operations on the table might fail with “could not open file” errors.

- Ensure that creation of the init fork of an unlogged index is WAL-logged (Heikki Linnakangas)

While an unlogged index's main data fork is not WAL-logged, its init fork should be, to ensure that we have a consistent state to restore the index to after a crash. This step was missed if the init fork contains no data, which is a case not used by any standard index AM; but perhaps some extension behaves that way.

- Fix missing reinitializations of delay-checkpoint-end flags (`suyu.cmj`)

This could result in unnecessary delays of checkpoints, or in assertion failures in assert-enabled builds.

- Fix overly strict assertion in `jsonpath` code (David Rowley)

This assertion failed if a query applied the `.type()` operator to a `like_regex` result. There was no bug in non-assert builds.

- Avoid assertion failure when processing an empty statement via the extended query protocol in an already-aborted transaction (Tom Lane)
- Fix `contrib/fuzzystrmatch`'s `Soundex difference()` function to handle empty input sanely (Alexander Lakhin, Tom Lane)

An input string containing no alphabetic characters resulted in unpredictable output.

- Tighten whitespace checks in `contrib/hstore` input (Evan Jones)

In some cases, characters would be falsely recognized as whitespace and hence discarded.

- Disallow oversize input arrays with `contrib/intarray`'s `gist__int_ops` index opclass (Ankit Kumar Pandey, Alexander Lakhin)

Previously this code would report a `NOTICE` but press on anyway, creating an invalid index entry that presents a risk of crashes when the index is read.

- Avoid useless double decompression of GiST index entries in `contrib/intarray` (Konstantin Knizhnik, Matthias van de Meent, Tom Lane)
- Fix `contrib/pageinspect`'s `gist_page_items()` function to work when there are included index columns (Alexander Lakhin, Michael Paquier)

Previously, if the index has included columns, `gist_page_items()` would fail to display those values on index leaf pages, or crash outright on non-leaf pages.

- Fix `pg_dump` to correctly handle new-style SQL-language functions whose bodies require parse-time dependencies on unique indexes (Tom Lane)

Such cases can arise from `GROUP BY` and `ON CONFLICT` clauses, for example. The function must then be postponed until after the unique index in the dump output, but `pg_dump` did not do that and instead printed a warning about “could not resolve dependency loop”.

- Ensure that `pg_index.indisreplident` is kept up-to-date in relation cache entries (Shruthi Gowda)

This value could be stale in some cases. There is no core code that relies on the relation cache's copy, so this is only a latent bug as far as Postgres itself is concerned; but there may be extensions for which it is a live bug.

## E.36. Release 14.8

**Release date:** 2023-05-11

This release contains a variety of fixes from 14.7. For information about new features in major release 14, see [Section E.44](#).

### E.36.1. Migration to Version 14.8

A dump/restore is not required for those running 14.X.

However, if you are upgrading from a version earlier than 14.4, see [Section E.40](#).

### E.36.2. Changes

- Prevent `CREATE SCHEMA` from defeating changes in `search_path` (Alexander Lakhin)

Within a `CREATE SCHEMA` command, objects in the prevailing `search_path`, as well as those in the newly-created schema, would be visible even within a called function or script that attempted to set a secure `search_path`. This could allow any user having permission to create a schema to hijack the privileges of a security definer function or extension script.

The PostgreSQL Project thanks Alexander Lakhin for reporting this problem. (CVE-2023-2454)

- Enforce row-level security policies correctly after inlining a set-returning function (Stephen Frost, Tom Lane)

If a set-returning SQL-language function refers to a table having row-level security policies, and it can be inlined into a calling query, those RLS policies would not get enforced properly in some cases involving re-using a cached plan under a different role. This could allow a user to see or modify rows that should have been invisible.

The PostgreSQL Project thanks Wolfgang Walther for reporting this problem. (CVE-2023-2455)

- Avoid crash when the new schema name is omitted in `CREATE SCHEMA` (Michael Paquier)

The SQL standard allows writing `CREATE SCHEMA AUTHORIZATION owner_name`, with the schema name defaulting to `owner_name`. However some code paths expected the schema name to be present and would fail.

- Fix enabling/disabling of cloned triggers in partitioned tables (Tom Lane)

`ALTER TABLE ... ENABLE/DISABLE TRIGGER USER` skipped cloned triggers, mistaking them for system triggers. Other variants of `ENABLE/DISABLE TRIGGER` would process them, but only after improperly enforcing a superuser check.

- Disallow altering composite types that are stored in indexes (Tom Lane)

`ALTER TYPE` disallows non-binary-compatible modifications of composite types if they are stored in any table columns. (Perhaps that will be allowed someday, but it hasn't happened yet; the locking implications of rewriting many tables are daunting.) We overlooked the possibility that an index might contain a composite type that doesn't also appear in its table.

- Disallow system columns as elements of foreign keys (Tom Lane)

Since the removal of `OID` as a system column, there is no plausible use-case for this, and various bits of code no longer support it. Disallow it rather than trying to fix all the cases.

- Ensure that `COPY TO` from an RLS-enabled parent table does not copy any rows from child tables (Antonin Houska)

The documentation is quite clear that `COPY TO` copies rows from only the named table, not any inheritance children it may have. However, if row-level security was enabled on the table then this stopped being true.

- Avoid possible crash when `array_position()` or `array_positions()` is passed an empty array (Tom Lane)
- Fix possible out-of-bounds fetch in `to_char()` (Tom Lane)

With bad luck this could have resulted in a server crash.

- Avoid buffer overread in `translate()` function (Daniil Anisimov)

When using the deletion feature, the function might fetch the byte just after the input string, creating a small risk of crash.

- Fix error cursor setting for parse errors in JSON string literals (Tom Lane)

Most cases in which a syntax error is detected in a string literal within a JSON value failed to set the error cursor appropriately. This led at least to an unhelpful error message (pointing to the token before the string, rather than the actual trouble spot), and could even result in a crash in v14 and later.

- Fix data corruption due to `vacuum_defer_cleanup_age` being larger than the current 64-bit xid (Andres Freund)

In v14 and later with non-default settings of `vacuum_defer_cleanup_age`, it was possible to compute a very large vacuum cleanup horizon xid, leading to vacuum removing rows that are still live. v12 and v13 have a lesser form of the same problem affecting only GiST indexes, which could lead to index pages getting recycled too early.

- Fix parser's failure to detect some cases of improperly-nested aggregates (Tom Lane)

This oversight could lead to executor failures for queries that should have been rejected as invalid.

- Fix data structure corruption during parsing of serial `SEQUENCE NAME` options (David Rowley)

This can lead to trouble if an event trigger captures the corrupted parse tree.

- Correctly update plan nodes' parallel-safety markings when moving initplans from one node to another (Tom Lane)

This planner oversight could lead to “subplan was not initialized” errors at runtime.

- Avoid failure with PlaceholderVars in extended-statistics code (Tom Lane)

Use of dependency-type extended statistics could fail with “PlaceholderVar found where not expected”.

- Disable the inverse-transition optimization for window aggregates when the call contains sub-SELECTs (David Rowley)

This optimization requires that the aggregate's argument expressions have repeatable results, which might not hold for a sub-SELECT.

- Fix oversights in execution of nested `ARRAY[]` constructs (Alexander Lakhin, Tom Lane)

Correctly detect overflow of the total space needed for the result array, avoiding a possible crash due to undersized output allocation. Also ensure that any trailing padding space in the result array is zeroed; while leaving garbage there is harmless for most purposes, it can result in odd behavior later.

- Prevent crash when updating a field within an array-of-domain-over-composite-type column (Dmitry Dolgov)
- Fix partition pruning logic for partitioning on boolean columns (David Rowley)

Pruning with a condition like `boolcol IS NOT TRUE` was done incorrectly, leading to possibly not returning rows in which `boolcol` is `NULL`. Also, the rather unlikely case of partitioning on `NOT boolcol` was handled incorrectly.

- Fix race condition in per-batch cleanup during parallel hash join (Thomas Munro, Melanie Plageman)

A crash was possible given unlucky timing and `parallel_leader_participation = off` (which is not the default).

- Recalculate `GENERATED` columns after an `EvalPlanQual` check (Tom Lane)

In `READ COMMITTED` isolation mode, the effects of a row update might need to get reapplied to a newer version of the row than the query found originally. If so, we need to recompute any `GENERATED` columns, in case they depend on columns that were changed by the concurrent update.

- Fix memory leak in Memoize plan execution (David Rowley)
- Fix buffer refcount leak when using batched inserts for a foreign table included in a partitioned tree (Alexander Pyhalov)
- Restore support for sub-millisecond `vacuum_cost_delay` settings (Thomas Munro)
- Don't balance vacuum cost delay when a table has a per-relation `vacuum_cost_delay` setting of zero (Masahiko Sawada)

Delay balancing is supposed to be disabled whenever autovacuum is processing a table with a per-relation `vacuum_cost_delay` setting, but this was done only for positive settings, not zero.

- Fix corner-case crashes when columns have been added to the end of a view (Tom Lane)
- Repair rare failure of `MULTIEXPR_SUBLINK` subplans in partitioned updates (Andres Freund, Tom Lane)

Use of the syntax `INSERT ... ON CONFLICT DO UPDATE SET (c1, ...) = (SELECT ...)` with a partitioned target table could result in failure if any child table is dissimilar from the parent (for example, different physical column order). This typically manifested as failure of consistency checks in the executor; but a crash or incorrect data updates are also possible.

- Fix handling of `DEFAULT` markers within a multi-row `INSERT ... VALUES` query on a view that has a `DO ALSO INSERT ... SELECT` rule (Dean Rasheed)

Such cases typically failed with “unrecognized node type” errors or assertion failures.

- Support references to `OLD` and `NEW` within subqueries in rule actions (Dean Rasheed, Tom Lane)

Such references are really lateral references, but the server could crash if the subquery wasn't explicitly marked with `LATERAL`. Arrange to do that implicitly when necessary.

- When decompiling a rule or SQL function body containing `INSERT/UPDATE/DELETE` within `WITH`, take care to print the correct alias for the target table (Tom Lane)
- Fix glitches in `SERIALIZABLE READ ONLY` optimization (Thomas Munro)

Transactions already marked as “doomed” confused the safe-snapshot optimization for `SERIALIZABLE READ ONLY` transactions. The optimization was unnecessarily skipped in some cases. In other cases an assertion failure occurred (but there was no problem in non-assert builds).

- Avoid leaking cache callback slots in the `pgoutput` logical decoding plugin (Shi Yu)

Multiple cycles of starting up and shutting down the plugin within a single session would eventually lead to an “out of `relcache_callback_list` slots” error.

- Avoid unnecessary calls to custom validators for index operator class options (Alexander Korotkov)  
This change fixes some cases where an unexpected error was thrown.
- Avoid useless work while scanning a multi-column BRIN index with multiple scan keys (Tomas Vondra)  
The existing code effectively considered only the last scan key while deciding whether a range matched, thus usually scanning more of the index than it needed to.
- Fix netmask handling in BRIN inet\_minmax\_multi\_ops opclass (Tomas Vondra)  
This error triggered an assertion failure in assert-enabled builds, but is mostly harmless in production builds.
- Fix dereference of dangling pointer during buffering build of a GiST index (Alexander Lakhin)  
This error seems to usually be harmless in production builds, as the fetched value is noncritical; but in principle it could cause a server crash.
- Ignore dropped columns and generated columns during logical replication of an update or delete action (Onder Kalaci, Shi Yu)  
Replication with the `REPLICA IDENTITY FULL` option failed if the table contained such columns.
- Correct the name of the wait event for SLRU buffer I/O for commit timestamps (Alexander Lakhin)  
This wait event is named `CommitTsBuffer` according to the documentation, but the code had it as `CommitTSBuffer`. Change the code to match the documentation, as that way is more consistent with the naming of related wait events.
- Re-activate reporting of wait event `SLRUFlushSync` (Thomas Munro)  
Reporting of this type of wait was accidentally removed in code refactoring.
- Avoid possible underflow when calculating how many WAL segments to keep (Kyotaro Horiguchi)  
This could result in not honoring `wal_keep_size` accurately.
- Support RSA-PSS certificates with SCRAM-SHA-256 channel binding (Jacob Champion, Heikki Linakangas)  
This feature requires building with OpenSSL 1.1.1 or newer. Both the server and libpq are affected.
- Avoid race condition with process ID tracking on Windows (Thomas Munro)  
The operating system could recycle a PID before the postmaster observed that that child process was gone. This could lead to tracking more than one child with the same PID, resulting in confusion.
- Add missing cases to `SPI_result_code_string()` (Dean Rasheed)
- Fix erroneous Valgrind markings in `AllocSetRealloc()` (Karina Litskevich)  
In the unusual case where the size of a large (>8kB) palloc chunk is decreased, a Valgrind-aware build would mismark the defined-ness state of the memory released from the chunk, possibly causing incorrect results during Valgrind testing.
- Avoid assertion failure when decoding a transactional logical replication message (Tomas Vondra)
- Avoid locale sensitivity when processing regular expression escapes (Jeff Davis)  
A backslash followed by a non-ASCII character could sometimes cause an assertion failure, depending on the prevailing locale.
- Avoid trying to write an empty WAL record in `log_newpage_range()` when the last few pages in the specified range are empty (Matthias van de Meent)

It is not entirely clear whether this case is reachable in released branches, but if it is then an assertion failure could occur.

- Fix session-lifespan memory leakage in `plpgsql DO` blocks that use cast expressions (Ajit Awekar, Tom Lane)
- Tighten array dimensionality checks when converting Perl list structures to multi-dimensional SQL arrays (Tom Lane)

`plperl` could misbehave when the nesting of sub-lists is inconsistent so that the data does not represent a rectangular array of values. Such cases now produce errors, but previously they could result in a crash or garbage output.

- Tighten array dimensionality checks when converting Python list structures to multi-dimensional SQL arrays (Tom Lane)

`plpython` could misbehave when dealing with empty sub-lists, or when the nesting of sub-lists is inconsistent so that the data does not represent a rectangular array of values. The former should result in an empty output array, and the latter in an error. But some cases resulted in a crash, and others in unexpected output.

- Fix unwinding of exception stack in `plpython` (Xing Guo)

Some rare failure cases could return without cleaning up the `PG_TRY` exception stack, risking a crash if another error was raised before the next stack level was unwound.

- Fix inconsistent GSS-encryption error handling in `libpq's PQconnectPoll()` (Michael Paquier)

With `gssencmode` set to `require`, the connection was not marked dead after a GSS initialization failure. Make it fail immediately, as the equivalent case for TLS encryption has long done.

- Fix possible data corruption in `ecpg` programs built with the `-C ORACLE` option (Kyotaro Horiguchi)

When `ecpg_get_data()` is called with `varcharsize` set to zero, it could write a terminating zero character into the last byte of the preceding field, truncating the data in that field.

- Fix `pg_dump` so that partitioned tables that are hash-partitioned on an enum-type column can be restored successfully (Tom Lane)

Since the hash codes for enum values depend on the OIDs assigned to the enum, they are typically different after a dump and restore, meaning that rows often need to go into a different partition than they were in originally. Users can work around that by specifying the `--load-via-partition-root` option; but since there is very little chance of success without that, teach `pg_dump` to apply it automatically to such tables.

Also, fix `pg_restore` to not try to `TRUNCATE` target tables before restoring into them when `--load-via-partition-root` mode is used. This avoids a hazard of deadlocks and lost data.

- Correctly detect non-seekable files on Windows (Juan José Santamaría Flecha, Michael Paquier, Daniel Watzinger)

This bug led to misbehavior when `pg_dump` writes to a pipe or `pg_restore` reads from one.

- In `pgbench's` “prepared” mode, prepare all the commands in a pipeline before starting the pipeline (Álvaro Herrera)

This avoids a failure when a `pgbench` script tries to start a serializable transaction inside a pipeline.

- In `contrib/amcheck's` heap checking code, deal correctly with tuples having zero `xmin` or `xmax` (Robert Haas)
- In `contrib/amcheck`, deal sanely with xids that appear to be before epoch zero (Andres Freund)

In cases of corruption we might see a wrapped-around 32-bit xid that appears to be before the first xid epoch. Promoting such a value to 64-bit form produced a value far in the future, resulting in

wrong reports. Return `FirstNormalFullTransactionId` in such cases so that things work reasonably sanely.

- In `contrib/hstore_plpython`, avoid crashing if the Python value to be transformed isn't a mapping (Dmitry Dolgov, Tom Lane)

This should give an error, but Python 3 changed some APIs in a way that caused the check to misbehave, allowing a crash to ensue.

- Require the `siglen` option of a GiST index on an `ltree` column, if specified, to be a multiple of 4 (Alexander Korotkov)

Other values result in misaligned accesses to index content, which is harmless on Intel-compatible hardware but can cause a crash on some other architectures.

- In `contrib/pageinspect`, add defenses against incorrect input for the `gist_page_items()` function (Dmitry Koval)
- Fix misbehavior in `contrib/pg_trgm` with an unsatisfiable regular expression (Tom Lane)

A regex such as `$foo` is legal but unsatisfiable; the regex compiler recognizes that and produces an empty NFA graph. Attempting to optimize such a graph into a `pg_trgm` GIN or GiST index qualification resulted in accessing off the end of a work array, possibly leading to crashes.

- Use the `--strip-unneeded` option when stripping static libraries with GNU-compatible `strip` (Tom Lane)

Previously, `make install-strip` used the `-x` option in this case. This change avoids misbehavior of `llvm-strip`, and gives slightly smaller output as well.

- Stop recommending auto-download of DTD files for building the documentation, and indeed disable it (Aleksander Alekseev, Peter Eisentraut, Tom Lane)

It appears no longer possible to build the SGML documentation without a local installation of the DocBook DTD files. Formerly `xsltproc` could download those files on-the-fly from `sourceforge.net`; but `sourceforge.net` now permits only HTTPS access, and no common version of `xsltproc` supports that. Hence, remove the bits of our documentation suggesting that that's possible or useful, and instead add `xsltproc`'s `--nonet` option to the build recipes.

- When running TAP tests in PGXS builds, use a saner location for the temporary `portlock` directory (Peter Eisentraut)

Place it under `tmp_check` in the build directory. With the previous coding, a PGXS build would try to place it in the installation directory, which is not necessarily writable.

- Update time zone data files to `tzdata` release 2023c for DST law changes in Egypt, Greenland, Morocco, and Palestine. (Tom Lane)

When observing Moscow time, Europe/Kirov and Europe/Volgograd now use the abbreviations MSK/MSD instead of numeric abbreviations, for consistency with other timezones observing Moscow time. Also, America/Yellowknife is no longer distinct from America/Edmonton; this affects some pre-1948 timestamps in that area.

## E.37. Release 14.7

**Release date:** 2023-02-09

This release contains a variety of fixes from 14.6. For information about new features in major release 14, see [Section E.44](#).

### E.37.1. Migration to Version 14.7

A dump/restore is not required for those running 14.X.

However, if you are upgrading from a version earlier than 14.4, see [Section E.40](#).

## E.37.2. Changes

- `libpq` can leak memory contents after GSSAPI transport encryption initiation fails (Jacob Champion)

A modified server, or an unauthenticated man-in-the-middle, can send a not-zero-terminated error message during setup of GSSAPI (Kerberos) transport encryption. `libpq` will then copy that string, as well as following bytes in application memory up to the next zero byte, to its error report. Depending on what the calling application does with the error report, this could result in disclosure of application memory contents. There is also a small probability of a crash due to reading beyond the end of memory. Fix by properly zero-terminating the server message. (CVE-2022-41862)

- Fix calculation of which `GENERATED` columns need to be updated in child tables during an `UPDATE` on a partitioned table or inheritance tree (Amit Langote, Tom Lane)

This fixes failure to update `GENERATED` columns that do not exist in the parent table, or that have different dependencies than are in the parent column's generation expression.

- Allow a `WITH RECURSIVE ... CYCLE` CTE to access its output column (Tom Lane)

A reference to the `SET` column from within the CTE would fail with “cache lookup failed for type 0”.

- Fix handling of pending inserts when doing a bulk insertion to a foreign table (Etsuro Fujita)

In some cases pending insertions were not flushed to the FDW soon enough, leading to logical inconsistencies, for example `BEFORE ROW` triggers not seeing rows they should be able to see.

- Allow `REPLICA IDENTITY` to be set on an index that's not (yet) valid (Tom Lane)

When `pg_dump` dumps a partitioned index that's marked `REPLICA IDENTITY`, it generates a command sequence that applies `REPLICA IDENTITY` before the partitioned index has been marked valid, causing restore to fail. There seems no very good reason to prohibit doing it in that order, so allow it. The marking will have no effect anyway until the index becomes valid.

- Fix handling of `DEFAULT` markers in rules that perform an `INSERT` from a multi-row `VALUES` list (Dean Rasheed)

In some cases a `DEFAULT` marker would not get replaced with the proper default-value expression, leading to an “unrecognized node type” error.

- Reject uses of undefined variables in `jsonpath` existence checks (Alexander Korotkov, David G. Johnston)

While `jsonpath` match operators threw an error for an undefined variable in the path pattern, the existence operators silently treated it as a match.

- Fix `jsonb` subscripting to cope with toasted subscript values (Tom Lane, David G. Johnston)

Using a text value fetched directly from a table as a `jsonb` subscript was likely to fail. Fetches would usually not find any matching element. Assignments could store the value with a garbage key, although keys long enough to cause that problem are probably rare in the field.

- Fix edge-case data corruption in parallel hash joins (Dmitry Astapov)

If the final chunk of a large tuple being written out to a temporary file was exactly 32760 bytes, it would be corrupted due to a fencepost bug. The query would typically fail later with corrupted-data symptoms.

- Honor non-default settings of `checkpoint_completion_target` (Bharath Rupireddy)

Internal state was not updated after a change in `checkpoint_completion_target`, possibly resulting in performing checkpoint I/O faster or slower than desired, especially if that setting was changed on-the-fly.

- Log the correct ending timestamp in `recovery_target_xid` mode (Tom Lane)

When ending recovery based on the `recovery_target_xid` setting with `recovery_target_inclusive = off`, we printed an incorrect timestamp (always 2000-01-01) in the “recovery stopping before ... transaction” log message.

- Improve error reporting for some buffered file read failures (Peter Eisentraut)

Correctly report a short read, giving the numbers of bytes desired and actually read, instead of reporting an irrelevant error code. Most places got this right already, but some recently-written replication logic did not.

- In extended query protocol, avoid an immediate commit after `ANALYZE` if we're running a pipeline (Tom Lane)

If there's not been an explicit `BEGIN TRANSACTION`, `ANALYZE` would take it on itself to commit, which should not happen within a pipelined series of commands.

- Reject cancel request packets having the wrong length (Andrey Borodin)

The server would process a cancel request even if its length word was too small. This led to reading beyond the end of the allocated buffer. In theory that could cause a segfault, but it seems quite unlikely to happen in practice, since the buffer would have to be very close to the end of memory. The more likely outcome was a bogus log message about wrong backend PID or cancel code. Complain about the wrong length, instead.

- Add recursion and looping defenses in subquery pullup (Tom Lane)

A contrived query can result in deep recursion and unreasonable amounts of time spent trying to flatten subqueries. A proper fix for that seems unduly invasive for a back-patch, but we can at least add stack depth checks and an interrupt check to allow the query to be cancelled.

- Fix planner issues when combining Memoize nodes with partitionwise joins or parameterized nest-loops (Richard Guo)

These errors could lead to not using Memoize in contexts where it would be useful, or possibly to wrong query plans.

- Fix partitionwise-join code to tolerate failure to produce a plan for each partition (Tom Lane)

This could result in “could not devise a query plan for the given query” errors.

- Limit the amount of cleanup work done by `get_actual_variable_range` (Simon Riggs)

Planner runs occurring just after deletion of a large number of tuples appearing at the end of an index could expend significant amounts of work setting the “killed” bits for those index entries. Limit the amount of work done in any one query by giving up on this process after examining 100 heap pages. All the cleanup will still happen eventually, but without so large a performance hiccup.

- Fix under-parenthesized display of `AT TIME ZONE` constructs (Tom Lane)

This could result in dump/restore failures for rules or views in which an argument of `AT TIME ZONE` is itself an expression.

- Prevent clobbering of cached parsetrees for utility statements in SQL functions (Tom Lane, Daniel Gustafsson)

If a SQL-language function executes the same utility command more than once within a single calling query, it could crash or report strange errors such as “unrecognized node type”.

- Ensure that execution of full-text-search queries can be cancelled while they are performing phrase matches (Tom Lane)
- Fix memory leak in hashing strings with nondeterministic collations (Jeff Davis)
- Fix deadlock between `DROP DATABASE` and logical replication worker process (Hou Zhijie)

This was caused by an ill-advised choice to block interrupts while creating a logical replication slot in the worker. In version 15 that could lead to an undetected deadlock. In version 14, no deadlock has been observed, but it's still a bad idea to block interrupts while waiting for network I/O.

- Clean up the libpq connection object after a failed replication connection attempt (Andres Freund)

The previous coding leaked the connection object. In background code paths that's pretty harmless because the calling process will give up and exit. But in commands such as `CREATE SUBSCRIPTION`, such a failure resulted in a small session-lifespan memory leak.

- In hot-standby servers, reduce processing effort for tracking XIDs known to be active on the primary (Simon Riggs, Michail Nikolaev)

Insufficiently-aggressive cleanup of the `KnownAssignedXids` array could lead to poor performance, particularly when `max_connections` is set to a large value on the standby.

- Ignore invalidated logical-replication slots while determining oldest catalog xmin (Sirisha Chamarthi)

A replication slot could prevent cleanup of dead tuples in the system catalogs even after it becomes invalidated due to exceeding `max_slot_wal_keep_size`. Thus, failure of a replication consumer could lead to indefinitely-large catalog bloat.

- In logical decoding, notify the remote node when a transaction is detected to have crashed (Hou Zhijie)

After a server restart, we'll re-stream the changes for transactions occurring shortly before the restart. Some of these transactions probably never completed; when we realize that one didn't we throw away the relevant decoding state locally, but we neglected to tell the subscriber about it. That led to the subscriber keeping useless streaming files until it's next restarted.

- Fix uninitialized-memory usage in logical decoding (Masahiko Sawada)

In certain cases, resumption of logical decoding could try to re-use XID data that had already been freed, leading to unpredictable behavior.

- Avoid rare "failed to acquire cleanup lock" panic during WAL replay of hash-index page split operations (Robert Haas)
- Advance a heap page's LSN when setting its all-visible bit during WAL replay (Jeff Davis)

Failure to do this left the page possibly different on standby servers than the primary, and violated some other expectations about when the LSN changes. This seems only a theoretical hazard so far as PostgreSQL itself is concerned, but it could upset third-party tools.

- Prevent unsafe usage of a relation cache entry's `rd_smgr` pointer (Amul Sul)

Remove various assumptions that `rd_smgr` would stay valid over a series of operations, by wrapping all uses of it in a function that will recompute it if needed. This prevents bugs occurring when an unexpected cache flush occurs partway through such a series.

- Fix `int64_div_fast_to_numeric()` to work for a wider range of inputs (Dean Rasheed)

This function misbehaved with some values of its second argument. No such usages exist in core PostgreSQL, but it's clearly a hazard for external modules, so repair.

- Fix latent buffer-overflow problem in `WaitEventSet` logic (Thomas Munro)

The `epoll`-based and `kqueue`-based implementations could ask the kernel for too many events if the size of their internal buffer was different from the size of the caller's output buffer. That case is not known to occur in released PostgreSQL versions, but this error is a hazard for external modules and future bug fixes.

- Avoid nominally-undefined behavior when accessing shared memory in 32-bit builds (Andres Freund)

clang's undefined-behavior sanitizer complained about use of a pointer that was less aligned than it should be. It's very unlikely that this would cause a problem in non-debug builds, but it's worth fixing for testing purposes.

- Fix assertion failure in BRIN minmax-multi opclasses (Tomas Vondra)

The assertion was overly strict, so this mistake was harmless in non-assert builds.

- Remove faulty assertion in useless-RESULT-RTE optimization logic (Tom Lane)
- Fix copy-and-paste errors in cache-lookup-failure messages for ACL checks (Justin Pryzby)

In principle these errors should never be reached. But if they are, some of them reported the wrong type of object.

- In `pg_dump`, avoid calling unsafe server functions before we have locks on the tables to be examined (Tom Lane, Gilles Darold)

`pg_dump` uses certain server functions that can fail if examining a table that gets dropped concurrently. Avoid this type of failure by ensuring that we obtain access share lock before inquiring too deeply into a table's properties, and that we don't apply such functions to tables we don't intend to dump at all.

- Fix `psql`'s `\sf` and `\ef` commands to handle SQL-language functions that have SQL-standard function bodies (Tom Lane)

These commands misidentified the start of the function body when it used new-style syntax.

- Fix tab completion of `ALTER FUNCTION/PROCEDURE/ROUTINE ... SET SCHEMA` (Dean Rasheed)
- Fix `contrib/seg` to not crash or print garbage if an input number has more than 127 digits (Tom Lane)
- Fix build on Microsoft Visual Studio 2013 (Tom Lane)

A previous patch supposed that all platforms of interest have `snprintf()`, but MSVC 2013 isn't quite there yet. Revert to using `sprintf()` on that platform.

- Fix compile failure in building PL/Perl with MSVC when using Strawberry Perl (Andrew Dunstan)
- Fix mismatch of PL/Perl built with MSVC versus a Perl library built with gcc (Andrew Dunstan)

Such combinations could previously fail with “loadable library and perl binaries are mismatched” errors.

- Suppress compiler warnings from Perl's header files (Andres Freund)

Our preferred compiler options provoke warnings about constructs appearing in recent versions of Perl's header files. When using gcc, we can suppress these warnings with a pragma.

- Fix `pg_waldump` to build on compilers that don't discard unused static-inline functions (Tom Lane)
- Update time zone data files to tzdata release 2022g for DST law changes in Greenland and Mexico, plus historical corrections for northern Canada, Colombia, and Singapore. (Tom Lane)

Notably, a new timezone `America/Ciudad_Juarez` has been split off from `America/Ojinaga`.

## E.38. Release 14.6

**Release date:** 2022-11-10

This release contains a variety of fixes from 14.5. For information about new features in major release 14, see [Section E.44](#).

### E.38.1. Migration to Version 14.6

A dump/restore is not required for those running 14.X.

However, if you are upgrading from a version earlier than 14.4, see [Section E.40](#).

## E.38.2. Changes

- Avoid rare PANIC during updates occurring concurrently with `VACUUM` (Tom Lane, Jeff Davis)

If a concurrent `VACUUM` sets the all-visible flag bit in a page that `UPDATE` or `DELETE` is in process of modifying, the updating command needs to clear that bit again; but some code paths failed to do so, ending in a PANIC exit and database restart.

This is known to be possible in versions 14 and 15. It may be only latent in previous branches.

- Fix handling of `DEFAULT` tokens that appear in a multi-row `VALUES` clause of an `INSERT` on an updatable view (Tom Lane)

This oversight could lead to “cache lookup failed for type” errors, or in older branches even to crashes.

- Disallow rules named `_RETURN` that are not `ON SELECT` (Tom Lane)

This avoids confusion between a view's `ON SELECT` rule and any other rules it may have.

- Fix resource management bug in saving tuples for `AFTER` triggers (Tom Lane)

Given the right circumstances, this manifested as a “tupdesc reference `NNNN` is not owned by resource owner” error followed by a PANIC exit.

- Avoid failure in `EXPLAIN VERBOSE` for a query using `SEARCH BREADTH FIRST` with constant initial values (Tom Lane)
- Fix construction of per-partition foreign key constraints while doing `ALTER TABLE ATTACH PARTITION` (Jehan-Guillaume de Rorthais, Álvaro Herrera)

Previously, incorrect or duplicate constraints could be constructed for the newly-added partition.

- Fix generation of constraint names for per-partition foreign key constraints (Jehan-Guillaume de Rorthais)

If the initially-given name is already in use for some constraint of the partition, a new one is selected; but it wasn't being spelled as intended.

- Fix incorrect matching of index expressions and predicates when creating a partitioned index (Richard Guo, Tom Lane)

While creating a partitioned index, we try to identify any existing indexes on the partitions that match the partitioned index, so that we can absorb those as child indexes instead of building new ones. Matching of expressions was not done right, so that a usable child index might be ignored, leading to creation of a duplicative index.

- Prevent WAL corruption after a standby promotion (Dilip Kumar, Robert Haas)

When a PostgreSQL instance performing archive recovery (but not using standby mode) is promoted, and the last WAL segment that it attempted to read ended in a partial record, the instance would write an invalid WAL segment on the new timeline.

- Fix mis-ordering of WAL operations in fast insert path for GIN indexes (Matthias van de Meent, Zhang Mingli)

This mistake is not known to have any negative consequences within core PostgreSQL, but it did cause issues for some extensions.

- Fix bugs in logical decoding when replay starts from a point between the beginning of a transaction and the beginning of its subtransaction (Masahiko Sawada, Kuroda Hayato)

These errors could lead to assertion failures in debug builds, and otherwise to memory leaks.

- Prevent examining system catalogs with the wrong snapshot during logical decoding (Masahiko Sawada)

If decoding begins partway through a transaction that modifies system catalogs, the decoder may not recognize that, causing it to fail to treat that transaction as in-progress for catalog lookups.

- Accept interrupts in more places during logical decoding (Amit Kapila, Masahiko Sawada)

This ameliorates problems with slow shutdown of replication workers.

- Prevent attempts to replicate into a foreign-table partition in replication workers (Shi Yu, Tom Lane)

Although partitioned tables can have foreign tables as partitions, replicating into such a partition isn't currently supported. The logical replication worker process would crash if it was attempted. Now, an error is thrown.

- Remove pointless check on replica identity setting of partitioned tables (Hou Zhijie)

What matters is the replica identity setting of the leaf partitions, so there's no need to throw error if it's not set on the parent.

- Avoid crash after function syntax error in replication workers (Maxim Orlov, Anton Melnikov, Masahiko Sawada, Tom Lane)

If a syntax error occurred in a SQL-language or PL/pgSQL-language `CREATE FUNCTION` or `DO` command executed in a logical replication worker, the worker process would crash with a null pointer dereference or assertion failure.

- Fix handling of read-write expanded datums that are passed to SQL functions (Tom Lane)

If a non-inlined SQL function uses a parameter in more than one place, and one of those functions expects to be able to modify read-write datums in place, then later uses of the parameter would observe the wrong value. (Within core PostgreSQL, the expanded-datum mechanism is only used for array and composite-type values; but extensions might use it for other structured types.)

- Fix type `circle`'s equality comparator to handle NaNs properly (Ranier Vilela)

If the left-hand circle had a floating-point NaN for its radius, it would be considered equal to a circle with the same center and any radius.

- In Snowball dictionaries, don't try to stem excessively-long words (Olly Betts, Tom Lane)

If the input word exceeds 1000 bytes, return it as-is after case folding, rather than trying to run it through the Snowball code. This restriction protects against a known recursion-to-stack-overflow problem in the Turkish stemmer, and it seems like good insurance against any other safety or performance issues that may exist in the Snowball stemmers. Such a long string is surely not a word in any human language, so it's doubtful that the stemmer would have done anything desirable with it anyway.

- Fix use-after-free hazard in string comparisons (Tom Lane)

Improper memory management in the string comparison functions could result in scribbling on no-longer-allocated buffers, potentially breaking things for whatever is using that memory now. This would only happen with fairly long strings (more than 1kB), and only if an ICU collation is in use.

- Add plan-time check for attempted access to a table that has no table access method (Tom Lane)

This prevents a crash in some catalog-corruption scenarios, for example use of a view whose `ON SELECT` rule is missing.

- Prevent postmaster crash when shared-memory state is corrupted (Tom Lane)

The postmaster process is supposed to survive and initiate a database restart if shared memory becomes corrupted, but one bit of code was being insufficiently cautious about that.

- Add some more defenses against recursion till stack overrun (Richard Guo, Tom Lane)
- Avoid misbehavior when choosing hash table size with very small `work_mem` and large tuples (Zhang Mingli)
- Avoid long-term memory leakage in the autovacuum launcher process (Reid Thompson)

The lack of field reports suggests that this problem is only latent in pre-v15 branches; but it's not very clear why, so back-patch the fix anyway.

- Improve PL/pgSQL's ability to handle parameters declared as `RECORD` (Tom Lane)

Build a separate function cache entry for each concrete type passed to the `RECORD` parameter during a session, much as we do for polymorphic parameters. This allows some usages to work that previously failed with errors such as “type of parameter does not match that when preparing the plan”.

- In `libpq`, handle single-row mode correctly when pipelining (Denis Laxalde)

The single-row flag was not reset at the correct time if pipeline mode was also active.

- Add missing guards for `NULL` connection pointer in `libpq` (Daniele Varrazzo, Tom Lane)

There's a convention that `libpq` functions should check for a `NULL PGconn` argument, and fail gracefully instead of crashing. `PQflush()` and `PQisnonblocking()` didn't get that memo, so fix them.

- In `ecpg`, fix omission of variable storage classes when multiple `varchar` or `bytea` variables are declared in the same declaration (Andrey Sokolov)

For example, `ecpg` translated `static varchar str1[10], str2[20], str3[30];` in such a way that only `str1` was marked `static`.

- Allow cross-platform tablespace relocation in `pg_basebackup` (Robert Haas)

Allow the remote path in `--tablespace-mapping` to be either a Unix-style or Windows-style absolute path, since the source server could be on a different OS than the local system.

- In `pg_stat_statements`, fix access to already-freed memory (zhaoqigui)

This occurred if `pg_stat_statements` tracked a `ROLLBACK` command issued via extended query protocol. In debug builds it consistently led to an assertion failure. In production builds there would often be no visible ill effect; but if the freed memory had already been reused, the likely result would be to store garbage for the query string.

- In `postgres_fdw`, ensure that target lists constructed for `EvalPlanQual` plans will have all required columns (Richard Guo, Etsuro Fujita)

This avoids “variable not found in subplan target list” errors in rare cases.

- Reject unwanted output from the platform's `uuid_create()` function (Nazir Bilal Yavuz)

The `uuid-oss` module expects `libc`'s `uuid_create()` to produce a version-1 UUID, but recent NetBSD releases produce a version-4 (random) UUID instead. Check for that, and complain if so. Drop the documentation's claim that the NetBSD implementation is usable for `uuid-oss`. (If a version-4 UUID is okay for your purposes, you don't need `uuid-oss` at all; just use `gen_random_uuid()`.)

- Include new Perl test modules in standard installations (Álvaro Herrera)

Add `PostgreSQL/Test/Cluster.pm` and `PostgreSQL/Test/Utils.pm` to the standard installation file set in pre-version-15 branches. This is for the benefit of extensions that want to use newly-written test code in older branches.

- On NetBSD, force dynamic symbol resolution at postmaster start (Andres Freund, Tom Lane)

This avoids a risk of deadlock in the dynamic linker on NetBSD 10.

- Fix incompatibilities with LLVM 15 (Thomas Munro, Andres Freund)
- Allow use of `__sync_lock_test_and_set()` for spinlocks on any machine (Tom Lane)

This eases porting to new machine architectures, at least if you're using a compiler that supports this GCC builtin function.

- Rename symbol `REF` to `REF_P` to avoid compile failure on recent macOS (Tom Lane)
- Avoid using `sprintf`, to avoid compile-time deprecation warnings (Tom Lane)
- Silence assorted compiler warnings from clang 15 and later (Tom Lane)
- Update time zone data files to tzdata release 2022f for DST law changes in Chile, Fiji, Iran, Jordan, Mexico, Palestine, and Syria, plus historical corrections for Chile, Crimea, Iran, and Mexico. (Tom Lane)

Also, the Europe/Kiev zone has been renamed to Europe/Kyiv. Also, the following zones have been merged into nearby, more-populous zones whose clocks have agreed with them since 1970: Antarctica/Vostok, Asia/Brunei, Asia/Kuala\_Lumpur, Atlantic/Reykjavik, Europe/Amsterdam, Europe/Copenhagen, Europe/Luxembourg, Europe/Monaco, Europe/Oslo, Europe/Stockholm, Indian/Christmas, Indian/Cocos, Indian/Kerguelen, Indian/Mahe, Indian/Reunion, Pacific/Chuuk, Pacific/Funafuti, Pacific/Majuro, Pacific/Pohnpei, Pacific/Wake and Pacific/Wallis. (This indirectly affects zones that were already links to one of these: Arctic/Longyearbyen, Atlantic/Jan\_Mayen, Iceland, Pacific/Ponape, Pacific/Truk, and Pacific/Yap.) America/Nipigon, America/Rainy\_River, America/Thunder\_Bay, Europe/Uzhgorod, and Europe/Zaporozhye were also merged into nearby zones after discovering that their claimed post-1970 differences from those zones seem to have been errors. In all these cases, the previous zone name remains as an alias; but the actual data is that of the zone that was merged into.

These zone mergers result in loss of pre-1970 timezone history for the merged zones, which may be troublesome for applications expecting consistency of `timestampz` display. As an example, the stored value `1944-06-01 12:00 UTC` would previously display as `1944-06-01 13:00:00+01` if the Europe/Stockholm zone is selected, but now it will read out as `1944-06-01 14:00:00+02`.

It is possible to build the time zone data files with options that will restore the older zone data, but that choice also inserts a lot of other old (and typically poorly-attested) zone data, resulting in more total changes from the previous release than accepting these upstream changes does. PostgreSQL has chosen to ship the tzdb data as-recommended, and so far as we are aware most major operating system distributions are doing likewise. However, if these changes cause significant problems for your application, a possible solution is to install a local build of the time zone data files using tzdb's backwards-compatibility options (see their `PACKRATDATA` and `PACKRATLIST` options).

## E.39. Release 14.5

**Release date:** 2022-08-11

This release contains a variety of fixes from 14.4. For information about new features in major release 14, see [Section E.44](#).

### E.39.1. Migration to Version 14.5

A dump/restore is not required for those running 14.X.

However, if you are upgrading from a version earlier than 14.4, see [Section E.40](#).

### E.39.2. Changes

- Do not let extension scripts replace objects not already belonging to the extension (Tom Lane)

This change prevents extension scripts from doing `CREATE OR REPLACE` if there is an existing object that does not belong to the extension. It also prevents `CREATE IF NOT EXISTS` in the same situation. This prevents a form of trojan-horse attack in which a hostile database user could become the

owner of an extension object and then modify it to compromise future uses of the object by other users. As a side benefit, it also reduces the risk of accidentally replacing objects one did not mean to.

The PostgreSQL Project thanks Sven Klemm for reporting this problem. (CVE-2022-2625)

- Fix replay of `CREATE DATABASE` WAL records on standby servers (Kyotaro Horiguchi, Asim R Praveen, Paul Guo)

Standby servers may encounter missing tablespace directories when replaying database-creation WAL records. Prior to this patch, a standby would fail to recover in such a case; however, such directories could be legitimately missing. Create the tablespace (as a plain directory), then check that it has been dropped again once replay reaches a consistent state.

- Support “in place” tablespaces (Thomas Munro, Michael Paquier, Álvaro Herrera)

Normally a Postgres tablespace is a symbolic link to a directory on some other filesystem. This change allows it to just be a plain directory. While this has no use for separating tables onto different filesystems, it is a convenient setup for testing. Moreover, it is necessary to support the `CREATE DATABASE` replay fix, which transiently creates a missing tablespace as an “in place” tablespace.

- Fix permissions checks in `CREATE INDEX` (Nathan Bossart, Noah Misch)

The fix for CVE-2022-1552 caused `CREATE INDEX` to apply the table owner's permissions while performing lookups of operator classes and other objects, where formerly the calling user's permissions were used. This broke dump/restore scenarios, because `pg_dump` issues `CREATE INDEX` before re-granting permissions.

- In extended query protocol, force an immediate commit after `CREATE DATABASE` and other commands that can't run in a transaction block (Tom Lane)

If the client does not send a Sync message immediately after such a command, but instead sends another command, any failure in that command would lead to rolling back the preceding command, typically leaving inconsistent state on-disk (such as a missing or extra database directory). The mechanisms intended to prevent that situation turn out to work for multiple commands in a simple-Query message, but not for a series of extended-protocol messages. To prevent inconsistency without breaking use-cases that work today, force an implicit commit after such commands.

- Fix race condition when checking transaction visibility (Simon Riggs)

`TransactionIdIsInProgress` could report `false` before the subject transaction is considered visible, leading to various misbehaviors. The race condition window is normally very narrow, but use of synchronous replication makes it much wider, because the wait for a synchronous replica happens in that window.

- Fix incorrect plans when sorting by an expression that contains a non-top-level set-returning function (Richard Guo, Tom Lane)
- Fix incorrect permissions-checking code for extended statistics (Richard Guo)

If there are extended statistics on a table that the user has only partial `SELECT` permissions on, some queries would fail with “unrecognized node type” errors.

- Fix extended statistics machinery to handle MCV-type statistics on boolean-valued expressions (Tom Lane)

Statistics collection worked fine, but a query containing such an expression in `WHERE` would fail with “unknown clause type”.

- Avoid planner core dump with `constant = ANY(array)` clauses when there are MCV-type extended statistics on the `array` variable (Tom Lane)
- Fix `ALTER TABLE ... ENABLE/DISABLE TRIGGER` to handle recursion correctly for triggers on partitioned tables (Álvaro Herrera, Amit Langote)

In certain cases, a “trigger does not exist” failure would occur because the command would try to adjust the trigger on a child partition that doesn't have it.

- Allow cancellation of `ANALYZE` while it is computing extended statistics (Tom Lane, Justin Pryzby)

In some scenarios with high statistics targets, it was possible to spend many seconds in an un-cancellable sort operation.

- Improve syntax error messages for type `jsonpath` (Andrew Dunstan)
- Ensure that `pg_stop_backup()` cleans up session state properly (Fujii Masao)

This omission could lead to assertion failures or crashes later in the session.

- Fix `trim_array()` to handle a zero-dimensional array argument sanely (Martin Kalcher)
- Fix join alias matching in `FOR [KEY] UPDATE/SHARE` clauses (Dean Rasheed)

In corner cases, a misleading error could be reported.

- Reject `ROW()` expressions and functions in `FROM` that have too many columns (Tom Lane)

Cases with more than about 1600 columns are unsupported, and have always failed at execution. However, it emerges that some earlier code could be driven to assertion failures or crashes by queries with more than 32K columns. Add a parse-time check to prevent that.

- Fix dumping of a view using a function in `FROM` that returns a composite type, when column(s) of the composite type have been dropped since the view was made (Tom Lane)

This oversight could lead to dump/reload or `pg_upgrade` failures, as the dumped view would have too many column aliases for the function.

- Disallow nested backup operations in logical replication walsenders (Fujii Masao)
- Fix memory leak in logical replication subscribers (Hou Zhijie)
- Fix logical replication's checking of replica identity when the target table is partitioned (Shi Yu, Hou Zhijie)

The replica identity columns have to be re-identified for the child partition.

- Fix failures to update cached schema data in a logical replication subscriber after a schema change on the publisher (Shi Yu, Hou Zhijie)
- Fix WAL consistency checking logic to correctly handle `BRIN_EVACUATE_PAGE` flags (Haiyang Wang)
- Fix erroneous assertion checks in shared hashtable management (Thomas Munro)
- Avoid assertion failure when `min_dynamic_shared_memory` is set to a non-default value (Thomas Munro)
- Arrange to clean up after commit-time errors within `SPI_commit()`, rather than expecting callers to do that (Peter Eisentraut, Tom Lane)

Proper cleanup is complicated and requires use of low-level facilities, so it's not surprising that no known caller got it right. This led to misbehaviors when a PL procedure issued `COMMIT` but a failure occurred (such as a deferred constraint check). To improve matters, redefine `SPI_commit()` as starting a new transaction, so that it becomes equivalent to `SPI_commit_and_chain()` except that you get default transaction characteristics instead of preserving the prior transaction's characteristics. To make this somewhat transparent API-wise, redefine `SPI_start_transaction()` as a no-op. All known callers of `SPI_commit()` immediately call `SPI_start_transaction()`, so they will not notice any change. Similar remarks apply to `SPI_rollback()`.

Also fix PL/Python, which omitted any handling of such errors at all, resulting in jumping out of the Python interpreter. This is reported to crash Python 3.11. Older Python releases leak some memory but seem okay with it otherwise.

- Improve libpq's handling of idle states in pipeline mode (Álvaro Herrera, Kyotaro Horiguchi)

This fixes “message type 0x33 arrived from server while idle” warnings, as well as possible loss of end-of-query NULL results from `PQgetResult()`.

- Avoid core dump in ecpglib with unexpected orders of operations (Tom Lane)

Certain operations such as `EXEC SQL PREPARE` would crash (rather than reporting an error as expected) if called before establishing any database connection.

- In ecpglib, avoid redundant `newlocale()` calls (Noah Misch)

Allocate a C locale object once per process when first connecting, rather than creating and freeing locale objects once per query. This mitigates a libc memory leak on AIX, and may offer some performance benefit everywhere.

- In psql's `\watch` command, echo a newline after cancellation with control-C (Pavel Stehule)

This prevents libedit (and possibly also libreadline) from becoming confused about which column the cursor is in.

- Fix `pg_upgrade` to detect non-upgradable usages of functions taking `anyarray` (Justin Pryzby)

Version 14 changed some built-in functions to take type `anycompatiblearray` instead of `anyarray`. While this is mostly transparent, user-defined aggregates and operators built atop these functions have to be declared with exactly matching types. The presence of an object referencing the old signature will cause `pg_upgrade` to fail, so change it to detect and report such cases before beginning the upgrade.

- Fix possible report of wrong error condition after `clone()` failure in `pg_upgrade` with `--clone` option (Justin Pryzby)

- Fix `contrib/pg_stat_statements` to avoid problems with very large query-text files on 32-bit platforms (Tom Lane)

- In `contrib/postgres_fdw`, prevent batch insertion when there are `WITH CHECK OPTION` constraints (Etsuro Fujita)

Such constraints cannot be checked properly if more than one row is inserted at a time.

- Fix `contrib/postgres_fdw` to detect failure to send an asynchronous data fetch query (Fujii Masao)

- Ensure that `contrib/postgres_fdw` sends constants of `regconfig` and other `reg*` types with proper schema qualification (Tom Lane)

- Block signals while allocating dynamic shared memory on Linux (Thomas Munro)

This avoids problems when a signal interrupts `posix_fallocate()`.

- Detect unexpected `EEXIST` error from `shm_open()` (Thomas Munro)

This avoids a possible crash on Solaris.

- Avoid using `signalfd()` on illumos systems (Thomas Munro)

This appears to trigger hangs and kernel panics, so avoid the function until a fix is available.

## E.40. Release 14.4

**Release date:** 2022-06-16

This release contains a variety of fixes from 14.3. For information about new features in major release 14, see [Section E.44](#).

### E.40.1. Migration to Version 14.4

A dump/restore is not required for those running 14.X.

However, if you have any indexes that were created using the `CONCURRENTLY` option under 14.X, you should re-index them after updating. See the first changelog entry below.

Also, if you are upgrading from a version earlier than 14.3, see [Section E.41](#).

### E.40.2. Changes

- Prevent possible corruption of indexes created or rebuilt with the `CONCURRENTLY` option (Álvaro Herrera)

An optimization added in v14 caused `CREATE INDEX ... CONCURRENTLY` and `REINDEX ... CONCURRENTLY` to sometimes miss indexing rows that were updated during the index build. Revert that optimization. It is recommended that any indexes made with the `CONCURRENTLY` option be rebuilt after installing this update. (Alternatively, rebuild them without `CONCURRENTLY`.)

- Harden Memoize plan node against non-deterministic equality functions (David Rowley)

Memoize could crash if a data type's equality or hash functions gave inconsistent results across different calls. Throw a runtime error instead.

- Fix incorrect cost estimates for Memoize plans (David Rowley)

This mistake could lead to Memoize being used when it isn't really the best plan, or to very long executor startup times due to initializing an overly-large hash table for a Memoize node.

- Fix queries in which a “whole-row variable” references the result of a function that returns a domain over composite type (Tom Lane)
- Fix “variable not found in subplan target list” planner error when pulling up a sub-`SELECT` that's referenced in a `GROUPING` function (Richard Guo)
- Prevent `pg_stat_get_subscription()` from possibly returning an extra row containing garbage values (Kuntal Ghosh)
- Fix `COPY FROM`'s error checking in the case where the database encoding is `SQL_ASCII` while the client's encoding is a multi-byte encoding (Heikki Linnakangas)

This mistake could lead to false complaints of invalidly-encoded input data.

- Avoid crashing if too many column aliases are attached to an `XMLTABLE` or `JSON_TABLE` construct (Álvaro Herrera)
- When decompiling a view or rule, show a `SELECT` output column's `AS "?column?"` alias clause if it could be referenced elsewhere (Tom Lane)

Previously, this auto-generated alias was always hidden; but there are corner cases where doing so results in a non-restorable view or rule definition.

- Report implicitly-created operator families to event triggers (Masahiko Sawada)

If `CREATE OPERATOR CLASS` results in the implicit creation of an operator family, that object was not reported to event triggers that should capture such events.

- Fix control file updates made when a restartpoint is running during promotion of a standby server (Kyotaro Horiguchi)

Previously, when the restartpoint completed it could incorrectly update the last-checkpoint fields of the control file, potentially leading to PANIC and failure to restart if the server crashes before the next normal checkpoint completes.

- Prevent triggering of standby's `wal_receiver_timeout` during logical replication of large transactions (Wang Wei, Amit Kapila)

If a large transaction on the primary server sends no data to the standby (perhaps because no table it changes is published), it was possible for the standby to timeout. Fix that by ensuring we send keepalive messages periodically in such situations.

- Prevent open-file leak when reading an invalid timezone abbreviation file (Kyotaro Horiguchi)

Such cases could result in harmless warning messages.

- Allow custom server parameters to have short descriptions that are NULL (Steve Chavez)

Previously, although extensions could choose to create such settings, some code paths would crash while processing them.

- Remove misguided SSL key file ownership check in libpq (Tom Lane)

In the previous minor releases, we copied the server's permission checking rules for SSL private key files into libpq. But we should not have also copied the server's file-ownership check. While that works in normal use-cases, it can result in an unexpected failure for clients running as root, and perhaps in other cases.

- Ensure ecpg reports server connection loss sanely (Tom Lane)

Misprocessing of a libpq-generated error result, such as a report of lost connection, would lead to printing “(null)” instead of a useful error message; or in older releases it would lead to a crash.

- Prevent crash after server connection loss in pg\_amcheck (Tom Lane)

Misprocessing of a libpq-generated error result, such as a report of lost connection, would lead to a crash.

- Adjust PL/Perl test case so it will work under Perl 5.36 (Dagfinn Ilmari Mannsåker)
- Avoid incorrectly using an out-of-date libldap\_r library when multiple OpenLDAP installations are present while building PostgreSQL (Tom Lane)

## E.41. Release 14.3

**Release date:** 2022-05-12

This release contains a variety of fixes from 14.2. For information about new features in major release 14, see [Section E.44](#).

### E.41.1. Migration to Version 14.3

A dump/restore is not required for those running 14.X.

However, if you have any GiST indexes on columns of type `ltree` (supplied by the `contrib/ltree` extension), you should re-index them after updating. See the second changelog entry below.

Also, if you are upgrading from a version earlier than 14.2, see [Section E.42](#).

### E.41.2. Changes

- Confine additional operations within “security restricted operation” sandboxes (Sergey Shinderuk, Noah Misch)

Autovacuum, `CLUSTER`, `CREATE INDEX`, `REINDEX`, `REFRESH MATERIALIZED VIEW`, and `pg_amcheck` activated the “security restricted operation” protection mechanism too late, or even not at all in some code paths. A user having permission to create non-temporary objects within a database could define an object that would execute arbitrary SQL code with superuser permissions the next time that autovacuum processed the object, or that some superuser ran one of the affected commands against it.

The PostgreSQL Project thanks Alexander Lakhin for reporting this problem. (CVE-2022-1552)

- Fix default signature length for `gist_ltree_ops` indexes (Tomas Vondra, Alexander Korotkov)

The default signature length (hash size) for GiST indexes on `ltree` columns was accidentally changed while upgrading that operator class to support operator class parameters. If any operations had been done on such an index without first upgrading the `ltree` extension to version 1.2, they were done assuming that the signature length was 28 bytes rather than the intended 8. This means it is very likely that such indexes are now corrupt. For safety we recommend re-indexing all GiST indexes on `ltree` columns after installing this update. (Note that GiST indexes on `ltree[]` columns, that is arrays of `ltree`, are not affected.)

- Stop using query-provided column aliases for the columns of whole-row variables that refer to plain tables (Tom Lane)

The column names in tuples produced by a whole-row variable (such as `tbl.*` in contexts other than the top level of a `SELECT` list) are now always those of the associated named composite type, if there is one. We'd previously attempted to make them track any column aliases that had been applied to the `FROM` entry the variable refers to. But that's semantically dubious, because really then the output of the variable is not at all of the composite type it claims to be. Previous attempts to deal with that inconsistency had bad results up to and including storing unreadable data on disk, so just give up on the whole idea.

In cases where it's important to be able to relabel such columns, a workaround is to introduce an extra level of sub-`SELECT`, so that the whole-row variable is referring to the sub-`SELECT`'s output and not to a plain table. Then the variable is of type `record` to begin with and there's no issue.

- Fix incorrect roundoff when extracting epoch values from intervals (Peter Eisentraut)

The new `numeric`-based code for `EXTRACT()` failed to yield results equivalent to the old `float`-based code, as a result of accidentally truncating the `DAYS_PER_YEAR` value to an integer.

- Defend against `pg_stat_get_replication_slot(NULL)` (Andres Freund)

This function should be marked strict in the catalog data, but it was not in v14, so add a run-time check instead.

- Fix incorrect output for types `timestampz` and `timetz` in `table_to_xmlschema()` and allied functions (Renan Soares Lopes)

The `xmlschema` output for these types included a malformed regular expression.

- Avoid core dump in parser for a `VALUES` clause with zero columns (Tom Lane)
- Fix planner failure when a Result plan node appears immediately underneath an Append node (Etsuro Fujita)

Recently-added code to support asynchronous remote queries failed to handle this case, leading to crashes or errors about unrecognized node types.

- Fix planner failure if a query using `SEARCH` or `CYCLE` features contains a duplicate CTE name (Tom Lane, Kyotaro Horiguchi)

When the name of the recursive `WITH` query is re-used within itself, the planner could crash or report odd errors such as "could not find attribute 2 in subquery targetlist".

- Fix planner errors for `GROUPING()` constructs that reference outer query levels (Richard Guo, Tom Lane)
- Fix plan generation for index-only scans on indexes with both returnable and non-returnable columns (Tom Lane)

The previous coding could try to read non-returnable columns in addition to the returnable ones. This was fairly harmless because it didn't actually do anything with the bogus values, but it fell foul of a recently-added error check that rejected such a plan.

- Avoid accessing a no-longer-pinned shared buffer while attempting to lock an outdated tuple during `EvalPlanQual` (Tom Lane)

The code would touch the buffer a couple more times after releasing its pin. In theory another process could recycle the buffer (or more likely, try to defragment its free space) as soon as the pin is gone, probably leading to failure to find the newer version of the tuple.

- Fix query-lifespan memory leak in an `IndexScan` node that is performing reordering (Aliaksandr Kalenik)
- Fix `ALTER FUNCTION` to support changing a function's parallelism property and its `SET`-variable list in the same command (Tom Lane)

The parallelism property change was lost if the same command also updated the function's `SET` clause.

- Tighten lookup of the index “owned by” a constraint (Tom Lane, Japin Li)

Some code paths mistook the index depended on by a foreign key constraint for one owned by a unique or primary key constraint, resulting in odd errors during certain `ALTER TABLE` operations on tables having foreign key constraints.

- Fix bogus errors from attempts to alter system columns of tables (Tom Lane)

The system should just tell you that you can't do it, but sometimes it would report “no owned sequence found” instead.

- Fix mis-sorting of table rows when `CLUSTERING` using an index whose leading key is an expression (Peter Geoghegan, Thomas Munro)

The table would be rebuilt with the correct data, but in an order having little to do with the index order.

- Prevent data loss if a system crash occurs shortly after a sorted GiST index build (Heikki Linnakangas)

The code path for building GiST indexes using sorting neglected to `fsync` the file upon completion. This could result in a corrupted index if the operating system crashed shortly later.

- Fix risk of deadlock failures while dropping a partitioned index (Jimmy Yih, Gaurab Dey, Tom Lane)

Ensure that the required table and index locks are taken in the standard order (parents before children, tables before indexes). The previous coding for `DROP INDEX` did it differently, and so could deadlock against concurrent queries taking these locks in the standard order.

- Fix race condition between `DROP TABLESPACE` and checkpointing (Nathan Bossart)

The checkpoint forced by `DROP TABLESPACE` could sometimes fail to remove all dead files from the tablespace's directory, leading to a bogus “tablespace is not empty” error.

- Fix possible trouble in crash recovery after a `TRUNCATE` command that overlaps a checkpoint (Kyotaro Horiguchi, Heikki Linnakangas, Robert Haas)

`TRUNCATE` must ensure that the table's disk file is truncated before the checkpoint is allowed to complete. Otherwise, replay starting from that checkpoint might find unexpected data in the supposedly-removed pages, possibly causing replay failure.

- Fix unsafe toast-data accesses during temporary object cleanup (Andres Freund)

Temporary-object deletion during server process exit could fail with “FATAL: cannot fetch toast data without an active snapshot”. This was usually harmless since the next use of that temporary schema would clean up successfully.

- Re-allow underscore as the first character in a custom parameter name (Japin Li)

Such names were unintentionally disallowed in v14.

- Add `regress` option for the `compute_query_id` parameter (Michael Paquier)

This is intended to facilitate testing, by allowing query IDs to be computed but not shown in `EXPLAIN` output.

- Improve wait logic in `RegisterSyncRequest` (Thomas Munro)

If we run out of space in the checkpointer sync request queue (which is hopefully rare on real systems, but is common when testing with a very small buffer pool), we wait for it to drain. While waiting, we should report that as a wait event so that users know what is going on, and also watch for postmaster death, since otherwise the loop might never terminate if the checkpointer has already exited.

- Wake up for latch events when the checkpointer is waiting between writes (Thomas Munro)

This improves responsiveness to backends sending sync requests. The change also creates a proper wait event class for these waits.

- Fix “PANIC: xlog flush request is not satisfied” failure during standby promotion when there is a missing WAL continuation record (Sami Imseih)
- Fix possibility of self-deadlock in hot standby conflict handling (Andres Freund)

With unlucky timing, the WAL-applying process could get stuck while waiting for some other process to release a buffer lock.

- Fix possible mis-identification of the correct ancestor relation to publish logical replication changes through (Tomas Vondra, Hou zj, Amit Kapila)

If `publish_via_partition_root` is enabled, and there are multiple publications naming different ancestors of the currently-modified relation, the wrong ancestor might be chosen for reporting the change.

- Ensure that logical replication apply workers can be restarted even when we're up against the `max_sync_workers_per_subscription` limit (Amit Kapila)

Faulty coding of the limit check caused a restarted worker to exit immediately, leaving fewer workers than there should be.

- Include unchanged replica identity key columns in the WAL log for an update, if they are stored out-of-line (Dilip Kumar, Amit Kapila)

Otherwise subscribers cannot see the values and will fail to replicate the update.

- Cope correctly with platforms that have no support for altering the server process's display in `ps(1)` (Andrew Dunstan)

Few platforms are like this (the only supported one is Cygwin), so we'd managed not to notice that refactoring introduced a potential memory clobber.

- Make the server more robust against missed timer interrupts (Michael Harris, Tom Lane)

An optimization added in v14 meant that if a server process somehow missed a timer interrupt, it would never again ask the kernel for another one, thus breaking timeout detection for the remainder of the session. This seems unduly fragile, so add a recovery path.

- Disallow execution of SPI functions during PL/Perl function compilation (Tom Lane)

Perl can be convinced to execute user-defined code during compilation of a PL/Perl function. However, it's not okay for such code to try to invoke SQL operations via SPI. That results in a crash, and if it didn't crash it would be a security hazard, because we really don't want code execution during function validation. Put in a check to give a friendlier error message instead.

- Make libpq accept root-owned SSL private key files (David Steele)

This change synchronizes libpq's rules for safe ownership and permissions of SSL key files with the rules the server has used since release 9.6. Namely, in addition to the current rules, allow the case where the key file is owned by root and has permissions `rw-r-----` or less. This is helpful for system-wide management of key files.

- Fix behavior of libpq's `PQisBusy()` function after a connection failure (Tom Lane)

If we'd detected a write failure, `PQisBusy()` would always return true, which is the wrong thing: we want input processing to carry on normally until we've read whatever is available from the server. The practical effect of this error is that applications using libpq's async-query API would typically detect connection loss only when `PQconsumeInput()` returns a hard failure. With this fix, a connection loss will normally be reported via an error `PGresult` object, which is a much cleaner behavior for most applications.

- Re-allow `database.schema.table` patterns in `psql`, `pg_dump`, and `pg_amcheck` (Mark Dilger)

Versions before v14 silently ignored all but the `schema` and `table` fragments of a pattern containing more than one dot. Refactoring in v14 accidentally broke that use-case. Reinstate it, but now complain if the first fragment is not the name of the current database.

- Make `pg_ctl` recheck postmaster aliveness while waiting for stop/restart/promote actions (Tom Lane)

`pg_ctl` would verify that the postmaster is alive as a side-effect of sending the stop or promote signal, but then it just naively waited to see the on-disk state change. If the postmaster died uncleanly without having removed its PID file or updated the control file, `pg_ctl` would wait until timeout. Instead make it recheck every so often that the postmaster process is still there.

- Fix error handling in `pg_waldump` (Kyotaro Horiguchi, Andres Freund)

While trying to read a WAL file to determine the WAL segment size, `pg_waldump` would report an incorrect error for the case of a too-short file. In addition, the file name reported in this and related error messages could be garbage.

- Ensure that `contrib/pageinspect` functions cope with all-zero pages (Michael Paquier)

This is a legitimate edge case, but the module was mostly unprepared for it. Arrange to return nulls, or no rows, as appropriate; that seems more useful than raising an error.

- In `contrib/pageinspect`, add defenses against incorrect page “special space” contents, tighten checks for correct page size, and add some missing checks that an index is of the expected type (Michael Paquier, Justin Pryzby, Julien Rouhaud)

These changes make it less likely that the module will crash on bad data.

- In `contrib/postgres_fdw`, disable batch insertion when `BEFORE INSERT ... FOR EACH ROW` triggers exist on the foreign table (Etsuro Fujita)

Such a trigger might query the table it's on and expect to see previously-inserted rows. With batch insertion, those rows might not be visible yet, so disable the feature to avoid unexpected behavior.

- In `contrib/postgres_fdw`, verify that `ORDER BY` clauses are safe to ship before requesting a remotely-ordered query, and include a `USING` clause if necessary (Ronan Dunklau)

This fix prevents situations where the remote server might sort in a different order than we intend. While sometimes that would be only cosmetic, it could produce thoroughly wrong results if the remote data is used as input for a locally-performed merge join.

- Fix configure to handle platforms that have `sys/epoll.h` but not `sys/signalfd.h` (Tom Lane)
- Update JIT code to work with LLVM 14 (Thomas Munro)
- Clean up assorted failures under clang's `-fsanitize=undefined` checks (Tom Lane, Andres Freund, Zhihong Yu)

Most of these changes are just for pro-forma compliance with the letter of the C and POSIX standards, and are unlikely to have any effect on production builds.

- Do not add OpenSSL dependencies to libpq's `pkg-config` file when building without OpenSSL (Fabrice Fontaine)
- Fix PL/Perl so it builds on C compilers that don't support statements nested within expressions (Tom Lane)
- Fix possible build failure of `pg_dumpall` on Windows, when not using MSVC to build (Andres Freund)
- In Windows builds, use `gendef` instead of `pexports` to build DEF files (Andrew Dunstan)

This adapts the build process to work on recent MSys tool chains.

- Prevent extra expansion of shell wildcard patterns in programs built under MinGW (Andrew Dunstan)

For some reason the C library provided by MinGW will expand shell wildcard characters in a program's command-line arguments by default. This is confusing, not least because it doesn't happen under MSVC, so turn it off.

- Update time zone data files to tzdata release 2022a for DST law changes in Palestine, plus historical corrections for Chile and Ukraine. (Tom Lane)

## E.42. Release 14.2

**Release date:** 2022-02-10

This release contains a variety of fixes from 14.1. For information about new features in major release 14, see [Section E.44](#).

### E.42.1. Migration to Version 14.2

A dump/restore is not required for those running 14.X.

However, some bugs have been found that may have resulted in corrupted indexes, as explained in the first two changelog entries. If any of those cases apply to you, it's recommended to reindex possibly-affected indexes after updating.

Also, if you are upgrading from a version earlier than 14.1, see [Section E.43](#).

### E.42.2. Changes

- Enforce standard locking protocol for TOAST table updates, to prevent problems with `REINDEX CONCURRENTLY` (Michael Paquier)

If applied to a TOAST table or TOAST table's index, `REINDEX CONCURRENTLY` tended to produce a corrupted index. This happened because sessions updating TOAST entries released their `ROW EXCLUSIVE` locks immediately, rather than holding them until transaction commit as all other updates do. The fix is to make TOAST updates hold the table lock according to the normal rule. Any existing corrupted indexes can be repaired by reindexing again.

- Fix corruption of HOT chains when a `RECENTLY_DEAD` tuple changes state to fully `DEAD` during page pruning (Andres Freund)

It was possible for `VACUUM` to remove a recently-dead tuple while leaving behind a redirect item that pointed to it. When the tuple's item slot is later re-used by some new tuple, that tuple would be seen as part of the pre-existing HOT chain, creating a form of index corruption. If this has hap-

pened, reindexing the table should repair the damage. However, this is an extremely low-probability scenario, so we do not recommend reindexing just on the chance that it might have happened.

- Fix crash in EvalPlanQual rechecks for tables with a mix of local and foreign partitions (Etsuro Fujita)
- Fix dangling pointer in `COPY TO` (Bharath Rupireddy)

This oversight could cause an incorrect error message or a crash after an error in `COPY`.

- Avoid null-pointer crash in `ALTER STATISTICS` when the statistics object is dropped concurrently (Tomas Vondra)
- Correctly handle alignment padding when extracting a range from a multirange (Alexander Korotkov)

This error could cause crashes when handling multiranges over variable-length data types.

- Fix over-optimistic use of hashing for anonymous `RECORD` data types (Tom Lane)

This prevents some cases of “could not identify a hash function for type record” errors.

- Fix incorrect plan creation for parallel single-child Append nodes (David Rowley)

In some cases the Append would be simplified away when it should not be, leading to wrong query results (duplicated rows).

- Fix index-only scan plans for cases where not all index columns can be returned (Tom Lane)

If an index has both returnable and non-returnable columns, and one of the non-returnable columns is an expression using a table column that appears in a returnable index column, then a query using that expression could result in an index-only scan plan that attempts to read the non-returnable column, instead of recomputing the expression from the returnable column as intended. The non-returnable column would read as NULL, resulting in wrong query results.

- Fix Memoize plan nodes to handle subplans that use parameters coming from above the Memoize (David Rowley)
- Fix Memoize plan nodes to work correctly with non-hashable join operators (David Rowley)
- Ensure that casting to an unspecified typmod generates a RelabelType node rather than a length-coercion function call (Tom Lane)

While the coercion function should do the right thing (nothing), this translation is undesirably inefficient.

- Fix checking of `anycompatible`-family data type matches (Tom Lane)

In some cases the parser would think that a function or operator with `anycompatible`-family polymorphic parameters matches a set of arguments that it really shouldn't match. In reported cases, that led to matching more than one operator to a call, leading to ambiguous-operator errors; but a failure later on is also possible.

- Fix WAL replay failure when database consistency is reached exactly at a WAL page boundary (Álvaro Herrera)
- Fix startup of a physical replica to tolerate transaction ID wraparound (Abhijit Menon-Sen, Tomas Vondra)

If a replica server is started while the set of active transactions on the primary crosses a wrap-around boundary (so that there are some newer transactions with smaller XIDs than older ones), the replica would fail with “out-of-order XID insertion in KnownAssignedXids”. The replica would retry, but could never get past that error.

- In logical replication, avoid double transmission of a child table's data (Hou Zhijie)

If a publication includes both child and parent tables, and has the `publish_via_partition_root` option set, subscribers uselessly initiated synchronization on both child and parent tables. Ensure that only the parent table is synchronized in such cases.

- Remove lexical limitations for SQL commands issued on a logical replication connection (Tom Lane)

The walsender process would fail for a SQL command containing an unquoted semicolon, or with dollar-quoted literals containing odd numbers of single or double quote marks, or when the SQL command starts with a comment. Moreover, faulty error recovery could lead to unexpected errors in later commands too.

- Ensure that replication origin timestamp is set while replicating a `ROLLBACK PREPARED` operation (Masahiko Sawada)
- Fix possible loss of the commit timestamp for the last subtransaction of a transaction (Alex Kingsborough, Kyotaro Horiguchi)
- Be sure to `fsync` the `pg_logical/mappings` subdirectory during checkpoints (Nathan Bossart)

On some filesystems this oversight could lead to losing logical rewrite status files after a system crash.

- Build extended statistics for partitioned tables (Justin Pryzby)

A previous bug fix disabled building of extended statistics for old-style inheritance trees, but it also prevented building them for partitioned tables, which was an unnecessary restriction. This change allows `ANALYZE` to compute values for statistics objects for partitioned tables. (But note that `autovacuum` does not process partitioned tables as such, so you must periodically issue manual `ANALYZE` on the partitioned table if you want to maintain such statistics.)

- Ignore extended statistics for inheritance trees (Justin Pryzby)

Currently, extended statistics values are only computed locally for each table, not for entire inheritance trees. However the values were mistakenly consulted when planning queries across inheritance trees, possibly resulting in worse-than-default estimates.

- Disallow altering data type of a partitioned table's columns when the partitioned table's row type is used as a composite type elsewhere (Tom Lane)

This restriction has long existed for regular tables, but through an oversight it was not checked for partitioned tables.

- Disallow `ALTER TABLE ... DROP NOT NULL` for a column that is part of a replica identity index (Haiying Tang, Hou Zhijie)

The same prohibition already existed for primary key indexes.

- Correctly update cached table state during `ALTER TABLE ADD PRIMARY KEY USING INDEX` (Hou Zhijie)

Concurrent sessions failed to update their opinion of whether the table has a primary key, possibly causing incorrect logical replication behavior.

- Correctly update cached table state when switching `REPLICA IDENTITY` index (Tang Haiying, Hou Zhijie)

Concurrent sessions failed to update their opinion of which index is the replica identity one, possibly causing incorrect logical replication behavior.

- Fix failure of SP-GiST indexes when the indexed column's data type is binary-compatible with the declared input type of the operator class (Tom Lane)

Such cases should work, but failed with “compress method must be defined when leaf type is different from input type”.

- Allow parallel vacuuming and concurrent index building to be ignored while computing oldest xmin (Masahiko Sawada)

Non-parallelized instances of these operations were already ignored, but the logic did not work for parallelized cases. Holding back the xmin horizon has undesirable effects such as delaying vacuum cleanup.

- Fix memory leak when updating expression indexes (Peter Geoghegan)

An `UPDATE` affecting many rows could consume significant amounts of memory.

- Avoid leaking memory during `REASSIGN OWNED BY` operations that reassign ownership of many objects (Justin Pryzby)
- Improve performance of walsenders sending logical changes by avoiding unnecessary cache accesses (Hou Zhijie)
- Fix display of `cert` authentication method's options in `pg_hba_file_rules` view (Magnus Hagner)

The `cert` authentication method implies `clientcert=verify-full`, but the `pg_hba_file_rules` view incorrectly reported `clientcert=verify-ca`.

- Ensure that the session targeted by `pg_log_backend_memory_contexts()` sends its results only to the server's log (Fujii Masao)

Previously, a sufficiently high setting of `client_min_messages` could result in the log message also being sent to the connected client. Since that client hadn't requested it, that would be surprising (and possibly a wire protocol violation).

- Fix display of whole-row variables appearing in `INSERT ... VALUES` rules (Tom Lane)

A whole-row variable would be printed as `"var.*"`, but that allows it to be expanded to individual columns when the rule is reloaded, resulting in different semantics. Attach an explicit cast to prevent that, as we do elsewhere.

- When reverse-listing a SQL-standard function body, display function parameters appropriately within `INSERT ... SELECT` (Tom Lane)

Previously, they'd come out as `$N` even when the parameter had a name.

- Fix one-byte buffer overrun when applying Unicode string normalization to an empty string (Michael Paquier)

The practical impact of this is limited thanks to alignment considerations; but in debug builds, a warning was raised.

- Fix or remove some incorrect assertions (Simon Riggs, Michael Paquier, Alexander Lakhin)

These errors should affect only debug builds, not production.

- Fix race condition that could lead to failure to localize error messages that are reported early in multi-threaded use of `libpq` or `ecpglib` (Tom Lane)
- Avoid calling `strerror` from `libpq`'s `PQcancel` function (Tom Lane)

`PQcancel` is supposed to be safe to call from a signal handler, but `strerror` is not safe. The faulty usage only occurred in the unlikely event of failure to send the cancel message to the server, perhaps explaining the lack of reports.

- Make `psql`'s `\password` command default to setting the password for `CURRENT_USER`, not the connection's original user name (Tom Lane)

This agrees with the documented behavior, and avoids probable permissions failure if `SET ROLE` or `SET SESSION AUTHORIZATION` has been done since the session began. To prevent confusion, the role name to be acted on is now included in the password prompt.

- Fix `psql \d` command's query for identifying parent triggers (Justin Pryzby)

The previous coding failed with “more than one row returned by a subquery used as an expression” if a partition had triggers and there were unrelated statement-level triggers of the same name on some parent partitioned table.

- Make `psql's \d` command sort a table's extended statistics objects by name not OID (Justin Pryzby)
- Fix `psql's` tab-completion of label values for enum types (Tom Lane)
- Fix failures on Windows when using the terminal as data source or destination (Dmitry Koval, Juan José Santamaría Flecha, Michael Paquier)

This affects `psql's \copy` command, as well as `pg_recvlogical` with `-f -`.

- In `psql` and some other client programs, avoid trying to invoke `gettext()` from a control-C signal handler (Tom Lane)

While no reported failures have been traced to this mistake, it seems highly unlikely to be a safe thing to do.

- Allow canceling the initial password prompt in `pg_receivewal` and `pg_recvlogical` (Tom Lane, Nathan Bossart)

Previously it was impossible to terminate these programs via control-C while they were prompting for a password.

- Fix `pg_dump's` dump ordering for user-defined casts (Tom Lane)

In rare cases, the output script might refer to a user-defined cast before it had been created.

- Fix `pg_dump's --inserts` and `--column-inserts` modes to handle tables containing both generated columns and dropped columns (Tom Lane)
- Fix possible mis-reporting of errors in `pg_dump` and `pg_basebackup` (Tom Lane)

The previous code failed to check for errors from some kernel calls, and could report the wrong `errno` values in other cases.

- Fix results of index-only scans on `contrib/btree_gist` indexes on `char(N)` columns (Tom Lane)

Index-only scans returned column values with trailing spaces removed, which is not the expected behavior. That happened because that's how the data was stored in the index. This fix changes the code to store `char(N)` values with the expected amount of space padding. The behavior of such an index will not change immediately unless you `REINDEX` it; otherwise space-stripped values will be gradually replaced over time during updates. Queries that do not use index-only scan plans will be unaffected in any case.

- Fix edge cases in `postgres_fdw's` handling of asynchronous queries (Etsuro Fujita)

These errors could lead to crashes or incorrect results when attempting to parallelize scans of foreign tables.

- Change `configure` to use Python's `sysconfig` module, rather than the deprecated `distutils` module, to determine how to build PL/Python (Peter Eisentraut, Tom Lane, Andres Freund)

With Python 3.10, this avoids `configure`-time warnings about `distutils` being deprecated and scheduled for removal in Python 3.12. Presumably, once 3.12 is out, `configure --with-python` would fail altogether. This future-proofing does come at a cost: `sysconfig` did not exist before Python 2.7, nor before 3.2 in the Python 3 branch, so it is no longer possible to build PL/Python against long-dead Python versions.

- Re-allow cross-compilation without OpenSSL (Tom Lane)

`configure` should assume that `/dev/urandom` will be available on the target system, but it failed instead.

- Fix PL/Perl compile failure on Windows with Perl 5.28 and later (Victor Wagner)
- Fix PL/Python compile failure with Python 3.11 and later (Peter Eisentraut)
- Add support for building with Visual Studio 2022 (Hans Buschmann)
- Allow the `.bat` wrapper scripts in our MSVC build system to be called without first changing into their directory (Anton Voloshin, Andrew Dunstan)

## E.43. Release 14.1

**Release date:** 2021-11-11

This release contains a variety of fixes from 14.0. For information about new features in major release 14, see [Section E.44](#).

### E.43.1. Migration to Version 14.1

A dump/restore is not required for those running 14.X.

However, note that installations using physical replication should update standby servers before the primary server, as explained in the third changelog entry below.

Also, several bugs have been found that may have resulted in corrupted indexes, as explained in the next several changelog entries. If any of those cases apply to you, it's recommended to reindex possibly-affected indexes after updating.

### E.43.2. Changes

- Make the server reject extraneous data after an SSL or GSS encryption handshake (Tom Lane)

A man-in-the-middle with the ability to inject data into the TCP connection could stuff some cleartext data into the start of a supposedly encryption-protected database session. This could be abused to send faked SQL commands to the server, although that would only work if the server did not demand any authentication data. (However, a server relying on SSL certificate authentication might well not do so.)

The PostgreSQL Project thanks Jacob Champion for reporting this problem. (CVE-2021-23214)

- Make libpq reject extraneous data after an SSL or GSS encryption handshake (Tom Lane)

A man-in-the-middle with the ability to inject data into the TCP connection could stuff some cleartext data into the start of a supposedly encryption-protected database session. This could probably be abused to inject faked responses to the client's first few queries, although other details of libpq's behavior make that harder than it sounds. A different line of attack is to exfiltrate the client's password, or other sensitive data that might be sent early in the session. That has been shown to be possible with a server vulnerable to CVE-2021-23214.

The PostgreSQL Project thanks Jacob Champion for reporting this problem. (CVE-2021-23222)

- Fix physical replication for cases where the primary crashes after shipping a WAL segment that ends with a partial WAL record (Álvaro Herrera)

If the primary did not survive long enough to finish writing the rest of the incomplete WAL record, then the previous crash-recovery logic had it back up and overwrite WAL starting from the beginning of the incomplete WAL record. This is problematic since standby servers may already have copies of that WAL segment. They will then see an inconsistent next segment, and will not be able to recover without manual intervention. To fix, do not back up over a WAL segment boundary when restarting after a crash. Instead write a new type of WAL record at the start of the next WAL segment, informing readers that the incomplete WAL record will never be finished and must be disregarded.

When applying this update, it's best to update standby servers before the primary, so that they will be ready to handle this new WAL record type if the primary happens to crash.

- Ensure that parallel `VACUUM` doesn't miss any indexes (Peter Geoghegan, Masahiko Sawada)

A parallel `VACUUM` would fail to process indexes that are below the `min_parallel_index_scan_size` cutoff, if the table also has at least two indexes that are above that size. This could result in those indexes becoming corrupt, since they'd still contain references to any heap entries removed by the `VACUUM`; subsequent queries using such indexes would be likely to return rows they shouldn't. This problem does not affect `autovacuum`, since it doesn't use parallel vacuuming. However, it is advisable to reindex any manually-vacuumed tables that have the right mix of index sizes.

- Fix `CREATE INDEX CONCURRENTLY` to wait for the latest prepared transactions (Andrey Borodin)

Rows inserted by just-prepared transactions might be omitted from the new index, causing queries relying on the index to miss such rows. The previous fix for this type of problem failed to account for `PREPARE TRANSACTION` commands that were still in progress when `CREATE INDEX CONCURRENTLY` checked for them. As before, in installations that have enabled prepared transactions (`max_prepared_transactions > 0`), it's recommended to reindex any concurrently-built indexes in case this problem occurred when they were built.

- Avoid race condition that can cause backends to fail to add entries for new rows to an index being built concurrently (Noah Misch, Andrey Borodin)

While it's apparently rare in the field, this case could potentially affect any index built or reindexed with the `CONCURRENTLY` option. It is recommended to reindex any such indexes to make sure they are correct.

- Fix `REINDEX CONCURRENTLY` to preserve operator class parameters that were attached to the target index (Michael Paquier)
- Fix incorrect creation of shared dependencies when cloning a database that contains non-builtin objects (Aleksander Alekseev)

The effects of this error are probably limited in practice. In principle, it could allow a role to be dropped while it still owns objects; but most installations would never want to drop a role that had been used for objects they'd added to `template1`.

- Ensure that the relation cache is invalidated for a table being attached to or detached from a partitioned table (Amit Langote, Álvaro Herrera)

This oversight could allow misbehavior of subsequent inserts/updates addressed directly to the partition, but only in currently-existing sessions.

- Fix corruption of parse tree while creating a range type (Alex Kozhemyakin, Sergey Shinderuk)

`CREATE TYPE` incorrectly freed an element of the parse tree, which could cause problems for a later event trigger, or if the `CREATE TYPE` command was stored in the plan cache and used again later.

- Fix updates of element fields in arrays of domain over composite (Tom Lane)

A command such as `UPDATE tab SET fld[1].subfld = val` failed if the array's elements were domains rather than plain composites.

- Disallow the combination of `FETCH FIRST WITH TIES` and `FOR UPDATE SKIP LOCKED` (David Christensen)

`FETCH FIRST WITH TIES` necessarily fetches one more row than requested, since it cannot stop until it finds a row that is not a tie. In our current implementation, if `FOR UPDATE` is used then that row will also get locked even though it is not returned. That results in undesirable behavior if the `SKIP LOCKED` option is specified. It's difficult to change this without introducing a different set of undesirable behaviors, so for now, forbid the combination.

- Disallow `ALTER INDEX index ALTER COLUMN col SET (options)` (Nathan Bossart, Michael Paquier)

While the parser accepted this, it's undocumented and doesn't actually work.

- Fix corner-case loss of precision in `numeric power()` (Dean Rasheed)

The result could be inaccurate when the first argument is very close to 1.

- Avoid choosing the wrong hash equality operator for Memoize plans (David Rowley)

This error could result in crashes or incorrect query results.

- Fix planner error with pulling up subquery expressions into function rangetable entries (Tom Lane)

If a function in `FROM` laterally references the output of some sub-`SELECT` earlier in the `FROM` clause, and we are able to flatten that sub-`SELECT` into the outer query, the expression(s) copied into the function expression were not fully processed. This could lead to crashes at execution.

- Avoid using MCV-only statistics to estimate the range of a column (Tom Lane)

There are corner cases in which `ANALYZE` will build a most-common-values (MCV) list but not a histogram, even though the MCV list does not account for all the observed values. In such cases, keep the planner from using the MCV list alone to estimate the range of column values.

- Fix restoration of a Portal's snapshot inside a subtransaction (Bertrand Drouvot)

If a procedure commits or rolls back a transaction, and then its next significant action is inside a new subtransaction, snapshot management went wrong, leading to a dangling pointer and probable crash. A typical example in PL/pgSQL is a `COMMIT` immediately followed by a `BEGIN ... EXCEPTION` block that performs a query.

- Clean up correctly if a transaction fails after exporting its snapshot (Dilip Kumar)

This oversight would only cause a problem if the same session attempted to export a snapshot again. The most likely scenario for that is creation of a replication slot (followed by rollback) and then creation of another replication slot.

- Prevent wraparound of overflowed-subtransaction tracking on standby servers (Kyotaro Horiguchi, Alexander Korotkov)

This oversight could cause significant performance degradation (manifesting as excessive SubtransSLRU traffic) on standby servers.

- Ensure that prepared transactions are properly accounted for during promotion of a standby server (Michael Paquier, Andres Freund)

There was a narrow window where a prepared transaction could be omitted from a snapshot taken by a concurrently-running session. If that session then used the snapshot to perform data updates, erroneous results or data corruption could occur.

- Fix “could not find RecursiveUnion” error when `EXPLAIN` tries to print a filter condition attached to a `WorkTableScan` node (Tom Lane)
- Ensure that the correct lock level is used when renaming a table (Nathan Bossart, Álvaro Herrera)

For historical reasons, `ALTER INDEX ... RENAME` can be applied to any sort of relation. The lock level required to rename an index is lower than that required to rename a table or other kind of relation, but the code got this wrong and would use the weaker lock level whenever the command is spelled `ALTER INDEX`.

- Avoid null-pointer-dereference crash when dropping a role that owns objects being dropped concurrently (Álvaro Herrera)
- Prevent “snapshot reference leak” warning when `lo_export()` or a related function fails (Heikki Linnakangas)

- Fix inefficient code generation for CoerceToDomain expression nodes (Ranier Vilela)
- Avoid  $O(N^2)$  behavior in some list-manipulation operations (Nathan Bossart, Tom Lane)

These changes fix slow processing in several scenarios, including: when a standby replays a transaction that held many exclusive locks on the primary; when many files are due to be unlinked after a checkpoint; when hash aggregation involves many batches; and when `pg_trgm` extracts indexable conditions from a complex regular expression. Only the first of these scenarios has actually been reported from the field, but they all seem like plausible consequences of inefficient list deletions.

- Add more defensive checks around B-tree posting list splits (Peter Geoghegan)

This change should help detect index corruption involving duplicate table TIDs.

- Avoid assertion failure when inserting NaN into a BRIN float8 or float4 minmax\_multi\_ops index (Tomas Vondra)

In production builds, such cases would result in a somewhat inefficient, but not actually incorrect, index.

- Allow the autovacuum launcher process to respond to `pg_log_backend_memory_contexts()` requests more quickly (Koyu Tanigawa)
- Fix memory leak in HMAC hash calculations (Sergey Shinderuk)
- Disallow setting `huge_pages` to on when `shared_memory_type` is `sysv` (Thomas Munro)

Previously, this setting was accepted, but it did nothing for lack of any implementation.

- Fix checking of query type in PL/pgSQL's `RETURN QUERY` statement (Tom Lane)

`RETURN QUERY` should accept any query that can return tuples, e.g. `UPDATE RETURNING`. v14 accidentally disallowed anything but `SELECT`; moreover, the `RETURN QUERY EXECUTE` variant failed to apply any query-type check at all.

- Fix `pg_dump` to dump non-global default privileges correctly (Neil Chen, Masahiko Sawada)

If a global (unrestricted) `ALTER DEFAULT PRIVILEGES` command revoked some present-by-default privilege, for example `EXECUTE` for functions, and then a restricted `ALTER DEFAULT PRIVILEGES` command granted that privilege again for a selected role or schema, `pg_dump` failed to dump the restricted privilege grant correctly.

- Make `pg_dump` acquire shared lock on partitioned tables that are to be dumped (Tom Lane)

This oversight was usually pretty harmless, since once `pg_dump` has locked any of the leaf partitions, that would suffice to prevent significant DDL on the partitioned table itself. However problems could ensue when dumping a childless partitioned table, since no relevant lock would be held.

- Fix crash in `pg_dump` when attempting to dump trigger definitions from a pre-8.3 server (Tom Lane)
- Fix incorrect filename in `pg_restore`'s error message about an invalid large object TOC file (Daniel Gustafsson)
- Ensure that `pgbench` exits with non-zero status after a socket-level failure (Yugo Nagata, Fabien Coelho)

The desired behavior is to finish out the run but then exit with status 2. Also, fix the reporting of such errors.

- Prevent `pg_amcheck` from checking temporary relations, as well as indexes that are invalid or not ready (Mark Dilger)

This avoids unhelpful checks of relations that will almost certainly appear inconsistent.

- Make `contrib/amcheck` skip unlogged tables when running on a standby server (Mark Dilger)

It's appropriate to do this since such tables will be empty, and unlogged indexes were already handled similarly.

- Change `contrib/pg_stat_statements` to read its “query texts” file in units of at most 1GB (Tom Lane)

Such large query text files are very unusual, but if they do occur, the previous coding would fail on Windows 64 (which rejects individual read requests of more than 2GB).

- Fix null-pointer crash when `contrib/postgres_fdw` tries to report a data conversion error (Tom Lane)
- Ensure that `GetSharedSecurityLabel()` can be used in a newly-started session that has not yet built its critical relation cache entries (Jeff Davis)
- When running a TAP test, include the module's own directory in `PATH` (Andrew Dunstan)

This allows tests to find built programs that are not installed, such as custom test drivers.

- Use the CLDR project's data to map Windows time zone names to IANA time zones (Tom Lane)

When running on Windows, `initdb` attempts to set the new cluster's `timezone` parameter to the IANA time zone matching the system's prevailing time zone. We were using a mapping table that we'd generated years ago and updated only fitfully; unsurprisingly, it contained a number of errors as well as omissions of recently-added zones. It turns out that CLDR has been tracking the most appropriate mappings, so start using their data. This change will not affect any existing installation, only newly-initialized clusters.

- Update time zone data files to `tzdata` release 2021e for DST law changes in Fiji, Jordan, Palestine, and Samoa, plus historical corrections for Barbados, Cook Islands, Guyana, Niue, Portugal, and Tonga. (Tom Lane)

Also, the Pacific/Enderbury zone has been renamed to Pacific/Kanton. Also, the following zones have been merged into nearby, more-populous zones whose clocks have agreed with them since 1970: Africa/Accra, America/Atikokan, America/Blanc-Sablon, America/Creston, America/Curacao, America/Nassau, America/Port\_of\_Spain, Antarctica/DumontDURville, and Antarctica/Syowa. In all these cases, the previous zone name remains as an alias.

## E.44. Release 14

**Release date:** 2021-09-30

### E.44.1. Overview

PostgreSQL 14 contains many new features and enhancements, including:

- Stored procedures can now return data via `OUT` parameters.
- The SQL-standard `SEARCH` and `CYCLE` options for common table expressions have been implemented.
- Subscripting can now be applied to any data type for which it is a useful notation, not only arrays. In this release, the `jsonb` and `hstore` types have gained subscripting operators.
- Range types have been extended by adding `multiranges`, allowing representation of noncontiguous data ranges.
- Numerous performance improvements have been made for parallel queries, heavily-concurrent workloads, partitioned tables, logical replication, and vacuuming.
- B-tree index updates are managed more efficiently, reducing index bloat.
- `VACUUM` automatically becomes more aggressive, and skips inessential cleanup, if the database starts to approach a transaction ID wraparound condition.

- Extended statistics can now be collected on expressions, allowing better planning results for complex queries.
- `libpq` now has the ability to pipeline multiple queries, which can boost throughput over high-latency connections.

The above items and other new features of PostgreSQL 14 are explained in more detail in the sections below.

## E.44.2. Migration to Version 14

A dump/restore using `pg_dumpall` or use of `pg_upgrade` or logical replication is required for those wishing to migrate data from any previous release. See [Section 18.6](#) for general information on migrating to new major releases.

Version 14 contains a number of changes that may affect compatibility with previous releases. Observe the following incompatibilities:

- User-defined objects that reference certain built-in array functions along with their argument types must be recreated (Tom Lane)

Specifically, `array_append()`, `array_prepend()`, `array_cat()`, `array_position()`, `array_positions()`, `array_remove()`, `array_replace()`, and `width_bucket()` used to take `anyarray` arguments but now take `anycompatiblearray`. Therefore, user-defined objects like aggregates and operators that reference those array function signatures must be dropped before upgrading, and recreated once the upgrade completes.

- Remove deprecated containment operators `@` and `~` for built-in [geometric data types](#) and contrib modules `cube`, `hstore`, `intarray`, and `seg` (Justin Pryzby)

The more consistently named `<@` and `@>` have been recommended for many years.

- Fix `to_tsquery()` and `websearch_to_tsquery()` to properly parse query text containing discarded tokens (Alexander Korotkov)

Certain discarded tokens, like underscore, caused the output of these functions to produce incorrect tsquery output, e.g., both `websearch_to_tsquery('pg_class pg')` and `to_tsquery('pg_class <-> pg')` used to output ( 'pg' & 'class' ) <-> 'pg', but now both output 'pg' <-> 'class' <-> 'pg'.

- Fix `websearch_to_tsquery()` to properly parse multiple adjacent discarded tokens in quotes (Alexander Korotkov)

Previously, quoted text that contained multiple adjacent discarded tokens was treated as multiple tokens, causing incorrect tsquery output, e.g., `websearch_to_tsquery('"aaa: bbb"')` used to output 'aaa' <2> 'bbb', but now outputs 'aaa' <-> 'bbb'.

- Change `EXTRACT()` to return type `numeric` instead of `float8` (Peter Eisentraut)

This avoids loss-of-precision issues in some usages. The old behavior can still be obtained by using the old underlying function `date_part()`.

Also, `EXTRACT(date)` now throws an error for units that are not part of the `date` data type.

- Change `var_samp()` and `stddev_samp()` with numeric parameters to return NULL when the input is a single NaN value (Tom Lane)

Previously NaN was returned.

- Return false for `has_column_privilege()` checks on non-existent or dropped columns when using attribute numbers (Joe Conway)

Previously such attribute numbers returned an invalid-column error.

- Fix handling of infinite [window function](#) ranges (Tom Lane)

Previously window frame clauses like `'inf' PRECEDING` AND `'inf' FOLLOWING` returned incorrect results.

- Remove factorial operators `!` and `!!`, as well as function `numeric_fac()` (Mark Dilger)

The `factorial()` function is still supported.

- Disallow `factorial()` of negative numbers (Peter Eisentraut)

Previously such cases returned 1.

- Remove support for [postfix](#) (right-unary) operators (Mark Dilger)

`pg_dump` and `pg_upgrade` will warn if postfix operators are being dumped.

- Allow `\D` and `\W` shorthands to match newlines in [regular expression](#) newline-sensitive mode (Tom Lane)

Previously they did not match newlines in this mode, but that disagrees with the behavior of other common regular expression engines. `[^[:digit:]]` or `[^[:word:]]` can be used to get the old behavior.

- Disregard constraints when matching regular expression [back-references](#) (Tom Lane)

For example, in `(^\d+).*\1`, the `^` constraint should be applied at the start of the string, but not when matching `\1`.

- Disallow `\w` as a range start or end in regular expression character classes (Tom Lane)

This previously was allowed but produced unexpected results.

- Require [custom server parameter](#) names to use only characters that are valid in unquoted SQL identifiers (Tom Lane)
- Change the default of the [password\\_encryption](#) server parameter to `scram-sha-256` (Peter Eisentraut)

Previously it was `md5`. All new passwords will be stored as SHA256 unless this server setting is changed or the password is specified in MD5 format. Also, the legacy (and undocumented) Boolean-like values which were previously synonyms for `md5` are no longer accepted.

- Remove server parameter `vacuum_cleanup_index_scale_factor` (Peter Geoghegan)

This setting was ignored starting in PostgreSQL version 13.3.

- Remove server parameter `operator_precedence_warning` (Tom Lane)

This setting was used for warning applications about PostgreSQL 9.5 changes.

- Overhaul the specification of `clientcert` in `pg_hba.conf` (Kyotaro Horiguchi)

Values `1/0/no-verify` are no longer supported; only the strings `verify-ca` and `verify-full` can be used. Also, disallow `verify-ca` if cert authentication is enabled since cert requires `verify-full` checking.

- Remove support for [SSL](#) compression (Daniel Gustafsson, Michael Paquier)

This was already disabled by default in previous PostgreSQL releases, and most modern OpenSSL and TLS versions no longer support it.

- Remove server and `libpq` support for the version 2 [wire protocol](#) (Heikki Linnakangas)

This was last used as the default in PostgreSQL 7.3 (released in 2002).

- Disallow single-quoting of the language name in the `CREATE/DROP LANGUAGE` command (Peter Eisentraut)
- Remove the `composite types` that were formerly created for sequences and toast tables (Tom Lane)
- Process doubled quote marks in `ecpg` SQL command strings correctly (Tom Lane)

Previously `'abc' 'def'` was passed to the server as `'abc' def'`, and `"abc" "def"` was passed as `"abc" def"`, causing syntax errors.

- Prevent the containment operators (`<@` and `@>`) for `intarray` from using GiST indexes (Tom Lane)

Previously a full GiST index scan was required, so just avoid that and scan the heap, which is faster. Indexes created for this purpose should be removed.

- Remove contrib program `pg_standby` (Justin Pryzby)
- Prevent `tablefunc`'s function `normal_rand()` from accepting negative values (Ashutosh Bapat)

Negative values produced undesirable results.

## E.44.3. Changes

Below you will find a detailed account of the changes between PostgreSQL 14 and the previous major release.

### E.44.3.1. Server

- Add predefined roles `pg_read_all_data` and `pg_write_all_data` (Stephen Frost)

These non-login roles can be used to give read or write permission to all tables, views, and sequences.

- Add predefined role `pg_database_owner` that contains only the current database's owner (Noah Misch)

This is especially useful in template databases.

- Remove temporary files after backend crashes (Euler Taveira)

Previously, such files were retained for debugging purposes. If necessary, deletion can be disabled with the new server parameter `remove_temp_files_after_crash`.

- Allow long-running queries to be canceled if the client disconnects (Sergey Cherkashin, Thomas Munro)

The server parameter `client_connection_check_interval` allows control over whether loss of connection is checked for intra-query. (This is supported on Linux and a few other operating systems.)

- Add an optional timeout parameter to `pg_terminate_backend()` (Magnus Hagander)
- Allow wide tuples to be always added to almost-empty heap pages (John Naylor, Floris van Nee)

Previously tuples whose insertion would have exceeded the page's `fill factor` were instead added to new pages.

- Add Server Name Indication (SNI) in SSL connection packets (Peter Eisentraut)

This can be disabled by turning off client connection option `sslsni`.

#### E.44.3.1.1. Vacuuming

- Allow vacuum to skip index vacuuming when the number of removable index entries is insignificant (Masahiko Sawada, Peter Geoghegan)

The vacuum parameter `INDEX_CLEANUP` has a new default of `auto` that enables this optimization.

- Allow vacuum to more eagerly add deleted btree pages to the free space map (Peter Geoghegan)  
Previously vacuum could only add pages to the free space map that were marked as deleted by previous vacuums.
- Allow vacuum to reclaim space used by unused trailing heap line pointers (Matthias van de Meent, Peter Geoghegan)
- Allow vacuum to be more aggressive in removing dead rows during minimal-locking index operations (Álvaro Herrera)

Specifically, `CREATE INDEX CONCURRENTLY` and `REINDEX CONCURRENTLY` no longer limit the dead row removal of other relations.

- Speed up vacuuming of databases with many relations (Tatsuhito Kasahara)
- Reduce the default value of `vacuum_cost_page_miss` to better reflect current hardware capabilities (Peter Geoghegan)
- Add ability to skip vacuuming of TOAST tables (Nathan Bossart)

`VACUUM` now has a `PROCESS_TOAST` option which can be set to false to disable TOAST processing, and `vacuumdb` has a `--no-process-toast` option.

- Have `COPY FREEZE` appropriately update page visibility bits (Anastasia Lubennikova, Pavan Deolasee, Jeff Janes)
- Cause vacuum operations to be more aggressive if the table is near xid or multixact wraparound (Masahiko Sawada, Peter Geoghegan)

This is controlled by `vacuum_failsafe_age` and `vacuum_multixact_failsafe_age`.

- Increase warning time and hard limit before transaction id and multi-transaction wraparound (Noah Misch)

This should reduce the possibility of failures that occur without having issued warnings about wraparound.

- Add per-index information to `autovacuum logging output` (Masahiko Sawada)

#### **E.44.3.1.2. Partitioning**

- Improve the performance of updates and deletes on partitioned tables with many partitions (Amit Langote, Tom Lane)

This change greatly reduces the planner's overhead for such cases, and also allows updates/deletes on partitioned tables to use execution-time partition pruning.

- Allow partitions to be `detached` in a non-blocking manner (Álvaro Herrera)

The syntax is `ALTER TABLE ... DETACH PARTITION ... CONCURRENTLY, and FINALIZE`.

- Ignore `COLLATE` clauses in partition boundary values (Tom Lane)

Previously any such clause had to match the collation of the partition key; but it's more consistent to consider that it's automatically coerced to the collation of the partition key.

#### **E.44.3.1.3. Indexes**

- Allow btree index additions to `remove expired index entries` to prevent page splits (Peter Geoghegan)

This is particularly helpful for reducing index bloat on tables whose indexed columns are frequently updated.

- Allow `BRIN` indexes to record multiple min/max values per range (Tomas Vondra)

This is useful if there are groups of values in each page range.

- Allow BRIN indexes to use bloom filters (Tomas Vondra)

This allows BRIN indexes to be used effectively with data that is not well-localized in the heap.

- Allow some [GiST](#) indexes to be built by presorting the data (Andrey Borodin)

Presorting happens automatically and allows for faster index creation and smaller indexes.

- Allow [SP-GiST](#) indexes to contain `INCLUDE`'d columns (Pavel Borisov)

#### **E.44.3.1.4. Optimizer**

- Allow hash lookup for `IN` clauses with many constants (James Coleman, David Rowley)

Previously the code always sequentially scanned the list of values.

- Increase the number of places [extended statistics](#) can be used for `OR` clause estimation (Tomas Vondra, Dean Rasheed)
- Allow extended statistics on expressions (Tomas Vondra)

This allows statistics on a group of expressions and columns, rather than only columns like previously. System view `pg_stats_ext_exprs` reports such statistics.

- Allow efficient heap scanning of a range of `TIDs` (Edmund Horner, David Rowley)

Previously a sequential scan was required for non-equality `TID` specifications.

- Fix `EXPLAIN CREATE TABLE AS` and `EXPLAIN CREATE MATERIALIZED VIEW` to honor `IF NOT EXISTS` (Bharath Rupireddy)

Previously, if the object already existed, `EXPLAIN` would fail.

#### **E.44.3.1.5. General Performance**

- Improve the speed of computing MVCC [visibility snapshots](#) on systems with many CPUs and high session counts (Andres Freund)

This also improves performance when there are many idle sessions.

- Add executor method to memoize results from the inner side of a nested-loop join (David Rowley)

This is useful if only a small percentage of rows is checked on the inner side. It can be disabled via server parameter [enable\\_memoize](#).

- Allow [window functions](#) to perform incremental sorts (David Rowley)
- Improve the I/O performance of parallel sequential scans (Thomas Munro, David Rowley)

This was done by allocating blocks in groups to [parallel workers](#).

- Allow a query referencing multiple [foreign tables](#) to perform foreign table scans in parallel (Robert Haas, Kyotaro Horiguchi, Thomas Munro, Etsuro Fujita)

[postgres\\_fdw](#) supports this type of scan if `async_capable` is set.

- Allow [analyze](#) to do page prefetching (Stephen Frost)

This is controlled by [maintenance\\_io\\_concurrency](#).

- Improve performance of [regular expression](#) searches (Tom Lane)
- Dramatically improve Unicode normalization performance (John Naylor)

This speeds `normalize()` and `IS NORMALIZED`.

- Add ability to use [LZ4 compression](#) on TOAST data (Dilip Kumar)

This can be set at the column level, or set as a default via server parameter `default_toast_compression`. The server must be compiled with `--with-lz4` to support this feature. The default setting is still `pglz`.

#### E.44.3.1.6. Monitoring

- If server parameter `compute_query_id` is enabled, display the query id in `pg_stat_activity`, `EXPLAIN VERBOSE`, `csvlog`, and optionally in `log_line_prefix` (Julien Rouhaud)

A query id computed by an extension will also be displayed.

- Improve logging of `auto-vacuum` and auto-analyze (Stephen Frost, Jakub Wartak)

This reports I/O timings for auto-vacuum and auto-analyze if `track_io_timing` is enabled. Also, report buffer read and dirty rates for auto-analyze.

- Add information about the original user name supplied by the client to the output of `log_connections` (Jacob Champion)

#### E.44.3.1.7. System Views

- Add system view `pg_stat_progress_copy` to report `COPY` progress (Josef Šimánek, Matthias van de Meent)
- Add system view `pg_stat_wal` to report WAL activity (Masahiro Ikeda)
- Add system view `pg_stat_replication_slots` to report replication slot activity (Masahiko Sawada, Amit Kapila, Vignesh C)

The function `pg_stat_reset_replication_slot()` resets slot statistics.

- Add system view `pg_backend_memory_contexts` to report session memory usage (Atsushi Torikoshi, Fujii Masao)
- Add function `pg_log_backend_memory_contexts()` to output the memory contexts of arbitrary backends (Atsushi Torikoshi)
- Add session statistics to the `pg_stat_database` system view (Laurenz Albe)
- Add columns to `pg_prepared_statements` to report generic and custom plan counts (Atsushi Torikoshi, Kyotaro Horiguchi)
- Add lock wait start time to `pg_locks` (Atsushi Torikoshi)
- Make the archiver process visible in `pg_stat_activity` (Kyotaro Horiguchi)
- Add wait event `WalReceiverExit` to report WAL receiver exit wait time (Fujii Masao)
- Implement information schema view `routine_column_usage` to track columns referenced by function and procedure default expressions (Peter Eisentraut)

#### E.44.3.1.8. Authentication

- Allow an SSL certificate's distinguished name (DN) to be matched for client certificate authentication (Andrew Dunstan)

The new `pg_hba.conf` option `clientname=DN` allows comparison with certificate attributes beyond the CN and can be combined with `ident maps`.

- Allow `pg_hba.conf` and `pg_ident.conf` records to span multiple lines (Fabien Coelho)

A backslash at the end of a line allows record contents to be continued on the next line.

- Allow the specification of a certificate revocation list (CRL) directory (Kyotaro Horiguchi)

This is controlled by server parameter `ssl_crl_dir` and libpq connection option `sslcrl_dir`. Previously only single CRL files could be specified.

- Allow passwords of an arbitrary length (Tom Lane, Nathan Bossart)

#### **E.44.3.1.9. Server Configuration**

- Add server parameter `idle_session_timeout` to close idle sessions (Li Japin)

This is similar to `idle_in_transaction_session_timeout`.

- Change `checkpoint_completion_target` default to 0.9 (Stephen Frost)

The previous default was 0.5.

- Allow `%P` in `log_line_prefix` to report the parallel group leader's PID for a parallel worker (Justin Pryzby)
- Allow `unix_socket_directories` to specify paths as individual, comma-separated quoted strings (Ian Lawrence Barwick)

Previously all the paths had to be in a single quoted string.

- Allow startup allocation of dynamic shared memory (Thomas Munro)

This is controlled by `min_dynamic_shared_memory`. This allows more use of huge pages.

- Add server parameter `huge_page_size` to control the size of huge pages used on Linux (Odin Ugedal)

#### **E.44.3.2. Streaming Replication and Recovery**

- Allow standby servers to be rewound via `pg_rewind` (Heikki Linnakangas)
- Allow the `restore_command` setting to be changed during a server reload (Sergei Kornilov)

You can also set `restore_command` to an empty string and reload to force recovery to only read from the `pg_wal` directory.

- Add server parameter `log_recovery_conflict_waits` to report long recovery conflict wait times (Bertrand Drouvot, Masahiko Sawada)
- Pause recovery on a hot standby server if the primary changes its parameters in a way that prevents replay on the standby (Peter Eisentraut)

Previously the standby would shut down immediately.

- Add function `pg_get_wal_replay_pause_state()` to report the recovery state (Dilip Kumar)

It gives more detailed information than `pg_is_wal_replay_paused()`, which still exists.

- Add new read-only server parameter `in_hot_standby` (Haribabu Kommi, Greg Nancarrow, Tom Lane)

This allows clients to easily detect whether they are connected to a hot standby server.

- Speed truncation of small tables during recovery on clusters with a large number of shared buffers (Kirk Jamison)
- Allow file system sync at the start of crash recovery on Linux (Thomas Munro)

By default, PostgreSQL opens and fsyncs each data file in the database cluster at the start of crash recovery. A new setting, `recovery_init_sync_method=syncfs`, instead syncs each filesystem used by the cluster. This allows for faster recovery on systems with many database files.

- Add function `pg_xact_commit_timestamp_origin()` to return the commit timestamp and replication origin of the specified transaction (Movead Li)
- Add the replication origin to the record returned by `pg_last_committed_xact()` (Movead Li)
- Allow replication `origin functions` to be controlled using standard function permission controls (Martín Marqués)

Previously these functions could only be executed by superusers, and this is still the default.

#### **E.44.3.2.1. Logical Replication**

- Allow logical replication to stream long in-progress transactions to subscribers (Dilip Kumar, Amit Kapila, Ajin Cherian, Tomas Vondra, Nikhil Sontakke, Stas Kelvich)

Previously transactions that exceeded `logical_decoding_work_mem` were written to disk until the transaction completed.

- Enhance the logical replication API to allow streaming large in-progress transactions (Tomas Vondra, Dilip Kumar, Amit Kapila)

The output functions begin with `stream.` `test_decoding` also supports these.

- Allow multiple transactions during table sync in logical replication (Peter Smith, Amit Kapila, Takamichi Osumi)
- Immediately WAL-log subtransaction and top-level `XID` association (Tomas Vondra, Dilip Kumar, Amit Kapila)

This is useful for logical decoding.

- Enhance logical decoding APIs to handle two-phase commits (Ajin Cherian, Amit Kapila, Nikhil Sontakke, Stas Kelvich)

This is controlled via `pg_create_logical_replication_slot()`.

- Add cache invalidation messages to the WAL during command completion when using logical replication (Dilip Kumar, Tomas Vondra, Amit Kapila)

This allows logical streaming of in-progress transactions. When logical replication is disabled, invalidation messages are generated only at transaction completion.

- Allow logical decoding to more efficiently process cache invalidation messages (Dilip Kumar)

This allows `logical decoding` to work efficiently in presence of a large amount of DDL.

- Allow control over whether logical decoding messages are sent to the replication stream (David Pirotte, Euler Taveira)
- Allow logical replication subscriptions to use binary transfer mode (Dave Cramer)

This is faster than text mode, but slightly less robust.

- Allow logical decoding to be filtered by `xid` (Markus Wanner)

#### **E.44.3.3. SELECT, INSERT**

- Reduce the number of keywords that can't be used as column labels without `AS` (Mark Dilger)

There are now 90% fewer restricted keywords.

- Allow an alias to be specified for `JOIN`'s `USING` clause (Peter Eisentraut)

The alias is created by writing `AS` after the `USING` clause. It can be used as a table qualification for the merged `USING` columns.

- Allow `DISTINCT` to be added to `GROUP BY` to remove duplicate `GROUPING SET` combinations (Vik Fearing)

For example, `GROUP BY CUBE (a,b), CUBE (b,c)` will generate duplicate grouping combinations without `DISTINCT`.

- Properly handle `DEFAULT` entries in multi-row `VALUES` lists in `INSERT` (Dean Rasheed)

Such cases used to throw an error.

- Add SQL-standard `SEARCH` and `CYCLE` clauses for [common table expressions](#) (Peter Eisentraut)

The same results could be accomplished using existing syntax, but much less conveniently.

- Allow column names in the `WHERE` clause of `ON CONFLICT` to be table-qualified (Tom Lane)

Only the target table can be referenced, however.

#### E.44.3.4. Utility Commands

- Allow `REFRESH MATERIALIZED VIEW` to use parallelism (Bharath Rupireddy)
- Allow `REINDEX` to change the tablespace of the new index (Alexey Kondratov, Michael Paquier, Justin Pryzby)

This is done by specifying a `TABLESPACE` clause. A `--tablespace` option was also added to `reindexdb` to control this.

- Allow `REINDEX` to process all child tables or indexes of a partitioned relation (Justin Pryzby, Michael Paquier)
- Allow index commands using `CONCURRENTLY` to avoid waiting for the completion of other operations using `CONCURRENTLY` (Álvaro Herrera)
- Improve the performance of `COPY FROM` in binary mode (Bharath Rupireddy, Amit Langote)
- Preserve SQL standard syntax for SQL-defined functions in [view definitions](#) (Tom Lane)

Previously, calls to SQL-standard functions such as `EXTRACT()` were shown in plain function-call syntax. The original syntax is now preserved when displaying a view or rule.

- Add the SQL-standard clause `GRANTED BY` to `GRANT` and `REVOKE` (Peter Eisentraut)
- Add `OR REPLACE` option for `CREATE TRIGGER` (Takamichi Osumi)

This allows pre-existing triggers to be conditionally replaced.

- Allow `TRUNCATE` to operate on foreign tables (Kazutaka Onishi, Kohei KaiGai)

The `postgres_fdw` module also now supports this.

- Allow publications to be more easily added to and removed from a subscription (Japin Li)

The new syntax is `ALTER SUBSCRIPTION ... ADD/DROP PUBLICATION`. This avoids having to specify all publications to add/remove entries.

- Add primary keys, unique constraints, and foreign keys to [system catalogs](#) (Peter Eisentraut)

These changes help GUI tools analyze the system catalogs. The existing unique indexes of catalogs now have associated `UNIQUE` or `PRIMARY KEY` constraints. Foreign key relationships are not actually stored or implemented as constraints, but can be obtained for display from the function `pg_get_catalog_foreign_keys()`.

- Allow `CURRENT_ROLE` every place `CURRENT_USER` is accepted (Peter Eisentraut)

#### E.44.3.5. Data Types

- Allow extensions and built-in data types to implement [subscripting](#) (Dmitry Dolgov)

Previously subscript handling was hard-coded into the server, so that subscripting could only be applied to array types. This change allows subscript notation to be used to extract or assign portions of a value of any type for which the concept makes sense.

- Allow subscripting of `JSONB` (Dmitry Dolgov)

JSONB subscribing can be used to extract and assign to portions of JSONB documents.

- Add support for [multirange data types](#) (Paul Jungwirth, Alexander Korotkov)

These are like range data types, but they allow the specification of multiple, ordered, non-overlapping ranges. An associated multirange type is automatically created for every range type.

- Add support for the [stemming](#) of languages Armenian, Basque, Catalan, Hindi, Serbian, and Yiddish (Peter Eisentraut)
- Allow [tsearch data files](#) to have unlimited line lengths (Tom Lane)

The previous limit was 4K bytes. Also remove function `t_readline()`.

- Add support for `Infinity` and `-Infinity` values in the [numeric data type](#) (Tom Lane)

Floating-point data types already supported these.

- Add [point operators](#) `<<|` and `|>>` representing strictly above/below tests (Emre Hasegeli)

Previously these were called `>^` and `<^`, but that naming is inconsistent with other geometric data types. The old names remain available, but may someday be removed.

- Add operators to add and subtract `LSN` and numeric (byte) values (Fujii Masao)
- Allow [binary data transfer](#) to be more forgiving of array and record `OID` mismatches (Tom Lane)
- Create composite array types for system catalogs (Wenjing Zeng)

User-defined relations have long had composite types associated with them, and also array types over those composite types. System catalogs now do as well. This change also fixes an inconsistency that creating a user-defined table in single-user mode would fail to create a composite array type.

### E.44.3.6. Functions

- Allow SQL-language [functions](#) and [procedures](#) to use SQL-standard function bodies (Peter Eisentraut)

Previously only string-literal function bodies were supported. When writing a function or procedure in SQL-standard syntax, the body is parsed immediately and stored as a parse tree. This allows better tracking of function dependencies, and can have security benefits.

- Allow [procedures](#) to have `OUT` parameters (Peter Eisentraut)
- Allow some array functions to operate on a mix of compatible data types (Tom Lane)

The functions `array_append()`, `array_prepend()`, `array_cat()`, `array_position()`, `array_positions()`, `array_remove()`, `array_replace()`, and `width_bucket()` now take `anycompatiblearray` instead of `anyarray` arguments. This makes them less fussy about exact matches of argument types.

- Add SQL-standard `trim_array()` function (Vik Fearing)

This could already be done with array slices, but less easily.

- Add bytea equivalents of `ltrim()` and `rtrim()` (Joel Jacobson)
- Support negative indexes in `split_part()` (Nikhil Benesch)

Negative values start from the last field and count backward.

- Add `string_to_table()` function to split a string on delimiters (Pavel Stehule)

This is similar to the `regexp_split_to_table()` function.

- Add `unistr()` function to allow Unicode characters to be specified as backslash-hex escapes in strings (Pavel Stehule)

This is similar to how Unicode can be specified in literal strings.

- Add `bit_xor()` XOR aggregate function (Alexey Bashtanov)
- Add function `bit_count()` to return the number of bits set in a bit or byte string (David Fetter)
- Add `date_bin()` function (John Naylor)

This function “bins” input timestamps, grouping them into intervals of a uniform length aligned with a specified origin.

- Allow `make_timestamp()/make_timestamptz()` to accept negative years (Peter Eisentraut)

Negative values are interpreted as BC years.

- Add newer regular expression `substring()` syntax (Peter Eisentraut)

The new SQL-standard syntax is `SUBSTRING(text SIMILAR pattern ESCAPE escapechar)`. The previous standard syntax was `SUBSTRING(text FROM pattern FOR escapechar)`, which is still accepted by PostgreSQL.

- Allow complemented character class escapes `\D`, `\S`, and `\W` within regular expression brackets (Tom Lane)
- Add `[[:word:]]` as a regular expression character class, equivalent to `\w` (Tom Lane)
- Allow more flexible data types for default values of `lead()` and `lag()` window functions (Vik Fearing)
- Make non-zero **floating-point values** divided by infinity return zero (Kyotaro Horiguchi)

Previously such operations produced underflow errors.

- Make floating-point division of NaN by zero return NaN (Tom Lane)

Previously this returned an error.

- Cause `exp()` and `power()` for negative-infinity exponents to return zero (Tom Lane)

Previously they often returned underflow errors.

- Improve the accuracy of geometric computations involving infinity (Tom Lane)
- Mark built-in type coercion functions as leakproof where possible (Tom Lane)

This allows more use of functions that require type conversion in security-sensitive situations.

- Change `pg_describe_object()`, `pg_identify_object()`, and `pg_identify_object_as_address()` to always report helpful error messages for non-existent objects (Michael Paquier)

#### **E.44.3.7. PL/pgSQL**

- Improve PL/pgSQL's **expression** and **assignment** parsing (Tom Lane)

This change allows assignment to array slices and nested record fields.

- Allow plpgsql's `RETURN QUERY` to execute its query using parallelism (Tom Lane)
- Improve performance of repeated **CALLs** within plpgsql procedures (Pavel Stehule, Tom Lane)

#### **E.44.3.8. Client Interfaces**

- Add **pipeline** mode to libpq (Craig Ringer, Matthieu Garrigues, Álvaro Herrera)

This allows multiple queries to be sent, only waiting for completion when a specific synchronization message is sent.

- Enhance libpq's `target_session_attrs` parameter options (Haribabu Kommi, Greg Nancarrow, Vignesh C, Tom Lane)

The new options are `read-only`, `primary`, `standby`, and `prefer-standby`.

- Improve the output format of libpq's `PQtrace()` (Aya Iwata, Álvaro Herrera)
- Allow an ECPG SQL identifier to be linked to a specific connection (Hayato Kuroda)

This is done via `DECLARE ... STATEMENT`.

#### E.44.3.9. Client Applications

- Allow `vacuumdb` to skip index cleanup and truncation (Nathan Bossart)

The options are `--no-index-cleanup` and `--no-truncate`.

- Allow `pg_dump` to dump only certain extensions (Guillaume Lelarge)

This is controlled by option `--extension`.

- Add `pgbench` `permute()` function to randomly shuffle values (Fabien Coelho, Hironobu Suzuki, Dean Rasheed)
- Include disconnection times in the reconnection overhead measured by `pgbench` with `-c` (Yugo Nagata)
- Allow multiple verbose option specifications (`-v`) to increase the logging verbosity (Tom Lane)

This behavior is supported by `pg_dump`, `pg_dumpall`, and `pg_restore`.

- Allow `psql`'s `\df` and `\do` commands to specify function and operator argument types (Greg Sabino Mullane, Tom Lane)

This helps reduce the number of matches printed for overloaded names.

- Add an access method column to `psql`'s `\d[i|m|t]+` output (Georgios Kokolatos)
- Allow `psql`'s `\dt` and `\di` to show TOAST tables and their indexes (Justin Pryzby)
- Add `psql` command `\dx` to list extended statistics objects (Tatsuro Yamada)
- Fix `psql`'s `\dT` to understand array syntax and backend grammar aliases, like `int` for `integer` (Greg Sabino Mullane, Tom Lane)
- When editing the previous query or a file with `psql`'s `\e`, or using `\ef` and `\ev`, ignore the results if the editor exits without saving (Laurenz Albe)

Previously, such edits would load the previous query into the query buffer, and typically execute it immediately. This was deemed to be probably not what the user wants.

- Improve tab completion (Vignesh C, Michael Paquier, Justin Pryzby, Georgios Kokolatos, Julien Rouhaud)

#### E.44.3.10. Server Applications

- Add command-line utility `pg_amcheck` to simplify running `contrib/amcheck` tests on many relations (Mark Dilger)
- Add `--no-instructions` option to `initdb` (Magnus Hagander)

This suppresses the server startup instructions that are normally printed.

- Stop `pg_upgrade` from creating `analyze_new_cluster` script (Magnus Hagander)

Instead, give comparable `vacuumdb` instructions.

- Remove support for the `postmaster -o` option (Magnus Hagander)

This option was unnecessary since all passed options could already be specified directly.

#### E.44.3.11. Documentation

- Rename "Default Roles" to "[Predefined Roles](#)" (Bruce Momjian, Stephen Frost)
- Add documentation for the `factorial()` function (Peter Eisentraut)

With the removal of the `!` operator in this release, `factorial()` is the only built-in way to compute a factorial.

#### E.44.3.12. Source Code

- Add configure option `--with-ssl={openssl}` to allow future choice of the SSL library to use (Daniel Gustafsson, Michael Paquier)

The spelling `--with-openssl` is kept for compatibility.

- Add support for [abstract Unix-domain sockets](#) (Peter Eisentraut)

This is currently supported on Linux and Windows.

- Allow Windows to properly handle files larger than four gigabytes (Juan José Santamaría Flecha)

For example this allows `COPY`, WAL files, and relation segment files to be larger than four gigabytes.

- Add server parameter `debug_discard_caches` to control cache flushing for test purposes (Craig Ringer)

Previously this behavior could only be set at compile time. To invoke it during `initdb`, use the new option `--discard-caches`.

- Various improvements in valgrind error detection ability (Álvaro Herrera, Peter Geoghegan)
- Add a test module for the regular expression package (Tom Lane)
- Add support for LLVM version 12 (Andres Freund)
- Change SHA1, SHA2, and MD5 hash computations to use the OpenSSL EVP API (Michael Paquier)

This is more modern and supports FIPS mode.

- Remove separate build-time control over the choice of random number generator (Daniel Gustafsson)

This is now always determined by the choice of SSL library.

- Add direct conversion routines between EUC\_TW and Big5 encodings (Heikki Linnakangas)
- Add collation version support for FreeBSD (Thomas Munro)
- Add `amadjustmembers` to the index access method API (Tom Lane)

This allows an index access method to provide validity checking during creation of a new operator class or family.

- Provide feature-test macros in `libpq-fe.h` for recently-added libpq features (Tom Lane, Álvaro Herrera)

Historically, applications have usually used compile-time checks of `PG_VERSION_NUM` to test whether a feature is available. But that's normally the server version, which might not be a good guide to libpq's version. `libpq-fe.h` now offers `#define` symbols denoting application-visible features added in v14; the intent is to keep adding symbols for such features in future versions.

### E.44.3.13. Additional Modules

- Allow subscripting of `hstore` values (Tom Lane, Dmitry Dolgov)
- Allow GiST/GIN `pg_trgm` indexes to do equality lookups (Julien Rouhaud)

This is similar to `LIKE` except no wildcards are honored.

- Allow the `cube` data type to be transferred in binary mode (KaiGai Kohei)
- Allow `pgstattuple_approx()` to report on TOAST tables (Peter Eisentraut)
- Add contrib module `pg_surgery` which allows changes to row visibility (Ashutosh Sharma)

This is useful for correcting database corruption.

- Add contrib module `old_snapshot` to report the `XID`/time mapping used by an active `old_snapshot_threshold` (Robert Haas)
- Allow `amcheck` to also check heap pages (Mark Dilger)

Previously it only checked B-Tree index pages.

- Allow `pageinspect` to inspect GiST indexes (Andrey Borodin, Heikki Linnakangas)
- Change `pageinspect` block numbers to be `bigints` (Peter Eisentraut)
- Mark `btree_gist` functions as parallel safe (Steven Winfield)

#### E.44.3.13.1. `pg_stat_statements`

- Move query hash computation from `pg_stat_statements` to the core server (Julien Rohaud)

The new server parameter `compute_query_id`'s default of `auto` will automatically enable query id computation when this extension is loaded.

- Cause `pg_stat_statements` to track top and nested statements separately (Julien Rohaud)

Previously, when tracking all statements, identical top and nested statements were tracked as a single entry; but it seems more useful to separate such usages.

- Add row counts for utility commands to `pg_stat_statements` (Fujii Masao, Katsuragi Yuta, Seino Yuki)
- Add `pg_stat_statements_info` system view to show `pg_stat_statements` activity (Katsuragi Yuta, Yuki Seino, Naoki Nakamichi)

#### E.44.3.13.2. `postgres_fdw`

- Allow `postgres_fdw` to `INSERT` rows in bulk (Takayuki Tsunakawa, Tomas Vondra, Amit Langote)
- Allow `postgres_fdw` to import table partitions if specified by `IMPORT FOREIGN SCHEMA ... LIMIT TO` (Matthias van de Meent)

By default, only the root of a partitioned table is imported.

- Add `postgres_fdw` function `postgres_fdw_get_connections()` to report open foreign server connections (Bharath Rupireddy)
- Allow control over whether foreign servers keep connections open after transaction completion (Bharath Rupireddy)

This is controlled by `keep_connections` and defaults to `on`.

- Allow `postgres_fdw` to reestablish foreign server connections if necessary (Bharath Rupireddy)

Previously foreign server restarts could cause foreign table access errors.

- Add `postgres_fdw` functions to discard cached connections (Bharath Rupireddy)

## E.44.4. Acknowledgments

The following individuals (in alphabetical order) have contributed to this release as patch authors, committers, reviewers, testers, or reporters of issues.

## E.45. Prior Releases

Release notes for prior versions can be found online. At the time of Postgres Pro Enterprise 14 release, these prior versions were supported:

- Postgres Pro Enterprise 13: <https://postgrespro.com/docs/enterprise/13/release.html>
- Postgres Pro Enterprise 12: <https://postgrespro.com/docs/enterprise/12/release.html>
- Postgres Pro Enterprise 11: <https://postgrespro.com/docs/enterprise/11/release.html>
- Postgres Pro Enterprise 10: <https://postgrespro.com/docs/enterprise/10/release.html>

---

# Appendix F. Additional Supplied Modules and Extensions Shipped in postgrespro-ent-14-contrib

This appendix, [Appendix G](#), and [Appendix I](#) contain information on the optional components available in the Postgres Pro Enterprise distribution. These include porting tools, analysis utilities, and plug-in features that are not part of the core Postgres Pro system. They are separate mainly because they address a limited audience or are too experimental to be part of the main source tree. This does not preclude their usefulness.

This appendix and [Appendix G](#) cover the extensions and other server plug-in modules. [Appendix I](#) covers the utility programs.

Many modules supply new user-defined functions, operators, or types. To make use of one of these modules, after you have installed the code you need to register the new SQL objects in the database system. This is done by executing a `CREATE EXTENSION` command. In a fresh database, you can simply do

```
CREATE EXTENSION module_name;
```

This command registers the new SQL objects in the current database only, so you need to run it in each database that you want the module's facilities to be available in. Alternatively, run it in database `template1` so that the extension will be copied into subsequently-created databases by default.

For all these modules, `CREATE EXTENSION` must be run by a database superuser, unless the module is considered “trusted”, in which case it can be run by any user who has `CREATE` privilege on the current database. Modules that are trusted are identified as such in the sections that follow. Generally, trusted modules are ones that cannot provide access to outside-the-database functionality.

Many modules allow you to install their objects in a schema of your choice. To do that, add `SCHEMA schema_name` to the `CREATE EXTENSION` command. By default, the objects will be placed in your current creation target schema, which in turn defaults to `public`.

Note, however, that some of these modules are not “extensions” in this sense, but are loaded into the server in some other way, for instance by way of [shared\\_preload\\_libraries](#). See the documentation of each module for details.

This appendix contains modules and extensions that are made available in Postgres Pro Enterprise as a separate subpackage `postgrespro-ent-14-contrib`.

## F.1. adminpack

`adminpack` provides a number of support functions which pgAdmin and other administration and management tools can use to provide additional functionality, such as remote management of server log files. Use of all these functions is only allowed to the superuser by default but may be allowed to other users by using the `GRANT` command.

The functions shown in [Table F.1](#) provide write access to files on the machine hosting the server. (See also the functions in [Table 9.97](#), which provide read-only access.) Only files within the database cluster directory can be accessed, unless the user is a superuser or given one of the `pg_read_server_files`, or `pg_write_server_files` roles, as appropriate for the function, but either a relative or absolute path is allowable.

**Table F.1. adminpack Functions**

| Function                              | Description                                                        |
|---------------------------------------|--------------------------------------------------------------------|
| <code>pg_catalog.pg_file_write</code> | <code>( filename text, data text, append boolean ) → bigint</code> |

| Function                                                                                                                   | Description                                                      |
|----------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------|
|                                                                                                                            | Writes, or appends to, a text file.                              |
| <code>pg_catalog.pg_file_sync</code> ( <i>filename</i> text ) → void                                                       | Flushes a file or directory to disk.                             |
| <code>pg_catalog.pg_file_rename</code> ( <i>oldname</i> text, <i>newname</i> text [, <i>archivename</i> text ] ) → boolean | Renames a file.                                                  |
| <code>pg_catalog.pg_file_unlink</code> ( <i>filename</i> text ) → boolean                                                  | Removes a file.                                                  |
| <code>pg_catalog.pg_logdir_ls</code> () → setof record                                                                     | Lists the log files in the <code>log_directory</code> directory. |

`pg_file_write` writes the specified *data* into the file named by *filename*. If *append* is false, the file must not already exist. If *append* is true, the file can already exist, and will be appended to if so. Returns the number of bytes written.

`pg_file_sync` fsyncs the specified file or directory named by *filename*. An error is thrown on failure (e.g., the specified file is not present). Note that `data_sync_retry` has no effect on this function, and therefore a PANIC-level error will not be raised even on failure to flush database files.

`pg_file_rename` renames a file. If *archivename* is omitted or NULL, it simply renames *oldname* to *newname* (which must not already exist). If *archivename* is provided, it first renames *newname* to *archivename* (which must not already exist), and then renames *oldname* to *newname*. In event of failure of the second rename step, it will try to rename *archivename* back to *newname* before reporting the error. Returns true on success, false if the source file(s) are not present or not writable; other cases throw errors.

`pg_file_unlink` removes the specified file. Returns true on success, false if the specified file is not present or the `unlink()` call fails; other cases throw errors.

`pg_logdir_ls` returns the start timestamps and path names of all the log files in the `log_directory` directory. The `log_filename` parameter must have its default setting (`postgresql-%Y-%m-%d_%H%M%S.log`) to use this function.

## F.2. amcheck

The `amcheck` module provides functions that allow you to verify the logical consistency of the structure of relations.

The B-Tree checking functions verify various *invariants* in the structure of the representation of particular relations. The correctness of the access method functions behind index scans and other important operations relies on these invariants always holding. For example, certain functions verify, among other things, that all B-Tree pages have items in “logical” order (e.g., for B-Tree indexes on `text`, index tuples should be in collated lexical order). If that particular invariant somehow fails to hold, we can expect binary searches on the affected page to incorrectly guide index scans, resulting in wrong answers to SQL queries. If the structure appears to be valid, no error is raised.

Verification is performed using the same procedures as those used by index scans themselves, which may be user-defined operator class code. For example, B-Tree index verification relies on comparisons made with one or more B-Tree support function 1 routines. See [Section 40.16.3](#) for details of operator class support functions.

Unlike the B-Tree checking functions which report corruption by raising errors, the heap checking function `verify_heapam` checks a table and attempts to return a set of rows, one row per corruption detected.

Despite this, if facilities that `verify_heapam` relies upon are themselves corrupted, the function may be unable to continue and may instead raise an error.

Permission to execute `amcheck` functions may be granted to non-superusers, but before granting such permissions careful consideration should be given to data security and privacy concerns. Although the corruption reports generated by these functions do not focus on the contents of the corrupted data so much as on the structure of that data and the nature of the corruptions found, an attacker who gains permission to execute these functions, particularly if the attacker can also induce corruption, might be able to infer something of the data itself from such messages.

### Note

Using `amcheck 1.1.1` is not recommended as the `bt_index_parent_check` function works incorrectly in that version.

## F.2.1. Functions

`bt_index_check(index regclass, heapallindexed boolean)` returns void

`bt_index_check(index regclass, heapallindexed boolean, checkunique boolean)` returns void

`bt_index_check` tests that its target, a B-Tree index, respects a variety of invariants. Example usage:

```
test=# SELECT bt_index_check(index => c.oid, heapallindexed => i.indisunique),
        c.relname,
        c.relpages
```

```
FROM pg_index i
JOIN pg_opclass op ON i.indclass[0] = op.oid
JOIN pg_am am ON op.opcmethod = am.oid
JOIN pg_class c ON i.indexrelid = c.oid
JOIN pg_namespace n ON c.relnamespace = n.oid
WHERE am.amname = 'btree' AND n.nspname = 'pg_catalog'
-- Don't check temp tables, which may be from another session:
AND c.relpersistence != 't'
-- Function may throw an error when this is omitted:
AND c.relkind = 'i' AND i.indisready AND i.indisvalid
ORDER BY c.relpages DESC LIMIT 10;
```

| bt_index_check | relname                         | relpages |
|----------------|---------------------------------|----------|
|                | pg_depend_reference_index       | 43       |
|                | pg_depend_depender_index        | 40       |
|                | pg_proc_proname_args_nsp_index  | 31       |
|                | pg_description_o_c_o_index      | 21       |
|                | pg_attribute_relid_attnam_index | 14       |
|                | pg_proc_oid_index               | 10       |
|                | pg_attribute_relid_attnum_index | 9        |
|                | pg_amproc_fam_proc_index        | 5        |
|                | pg_amop opr_fam_index           | 5        |
|                | pg_amop_fam_strat_index         | 5        |

(10 rows)

This example shows a session that performs verification of the 10 largest catalog indexes in the database “test”. Verification of the presence of heap tuples as index tuples is requested for the subset that are unique indexes. Since no error is raised, all indexes tested appear to be logically consistent. Naturally, this query could easily be changed to call `bt_index_check` for every index in the database where verification is supported.

`bt_index_check` acquires an `AccessShareLock` on the target index and the heap relation it belongs to. This lock mode is the same lock mode acquired on relations by simple `SELECT` statements. `bt_in-`

`bt_index_check` does not verify invariants that span child/parent relationships, but will verify the presence of all heap tuples as index tuples within the index when `heapallindexed` is `true`. `bt_index_check` with three arguments verifies unique constraints when `checkunique` is `true`. When a routine, lightweight test for corruption is required in a live production environment, using `bt_index_check` often provides the best trade-off between thoroughness of verification and limiting the impact on application performance and availability.

```
bt_index_parent_check(index regclass, heapallindexed boolean, rootdescend boolean) returns void
```

```
bt_index_parent_check(index regclass, heapallindexed boolean, rootdescend boolean, checkunique boolean) returns void
```

`bt_index_parent_check` tests that its target, a B-Tree index, respects a variety of invariants. Optionally, when the `heapallindexed` argument is `true`, the function verifies the presence of all heap tuples that should be found within the index. `bt_index_parent_check` with four arguments verifies unique constraints when `checkunique` is `true`. When the optional `rootdescend` argument is `true`, verification re-finds tuples on the leaf level by performing a new search from the root page for each tuple. The checks that can be performed by `bt_index_parent_check` are a superset of the checks that can be performed by `bt_index_check`. `bt_index_parent_check` can be thought of as a more thorough variant of `bt_index_check`: unlike `bt_index_check`, `bt_index_parent_check` also checks invariants that span parent/child relationships, including checking that there are no missing down-links in the index structure. `bt_index_parent_check` follows the general convention of raising an error if it finds a logical inconsistency or other problem.

A `ShareLock` is required on the target index by `bt_index_parent_check` (a `ShareLock` is also acquired on the heap relation). These locks prevent concurrent data modification from `INSERT`, `UPDATE`, and `DELETE` commands. The locks also prevent the underlying relation from being concurrently processed by `VACUUM`, as well as all other utility commands. Note that the function holds locks only while running, not for the entire transaction.

`bt_index_parent_check`'s additional verification is more likely to detect various pathological cases. These cases may involve an incorrectly implemented B-Tree operator class used by the index that is checked, or, hypothetically, undiscovered bugs in the underlying B-Tree index access method code. Note that `bt_index_parent_check` cannot be used when Hot Standby mode is enabled (i.e., on read-only physical replicas), unlike `bt_index_check`.

### Tip

`bt_index_check` and `bt_index_parent_check` both output log messages about the verification process at `DEBUG1` and `DEBUG2` severity levels. These messages provide detailed information about the verification process that may be of interest to PostgreSQL developers. Advanced users may also find this information helpful, since it provides additional context should verification actually detect an inconsistency. Running:

```
SET client_min_messages = DEBUG1;
```

in an interactive `psql` session before running a verification query will display messages about the progress of verification with a manageable level of detail.

```
verify_heapam(relation regclass, on_error_stop boolean, check_toast boolean, skip text, startblock bigint, endblock bigint, blkno OUT bigint, offnum OUT integer, attnum OUT integer, msg OUT text) returns setof record
```

Checks a table for structural corruption, where pages in the relation contain data that is invalidly formatted, and for logical corruption, where pages are structurally valid but inconsistent with the rest of the database cluster.

The following optional arguments are recognized:

`on_error_stop`

If true, corruption checking stops at the end of the first block in which any corruptions are found.

Defaults to false.

`check_toast`

If true, toasted values are checked against the target relation's TOAST table.

This option is known to be slow. Also, if the toast table or its index is corrupt, checking it against toast values could conceivably crash the server, although in many cases this would just produce an error.

Defaults to false.

`skip`

If not `none`, corruption checking skips blocks that are marked as all-visible or all-frozen, as specified. Valid options are `all-visible`, `all-frozen` and `none`.

Defaults to `none`.

`startblock`

If specified, corruption checking begins at the specified block, skipping all previous blocks. It is an error to specify a `startblock` outside the range of blocks in the target table.

By default, checking begins at the first block.

`endblock`

If specified, corruption checking ends at the specified block, skipping all remaining blocks. It is an error to specify an `endblock` outside the range of blocks in the target table.

By default, all blocks are checked.

For each corruption detected, `verify_heapam` returns a row with the following columns:

`blkno`

The number of the block containing the corrupt page.

`offnum`

The OffsetNumber of the corrupt tuple.

`attnum`

The attribute number of the corrupt column in the tuple, if the corruption is specific to a column and not the tuple as a whole.

`msg`

A message describing the problem detected.

## F.2.2. Optional *heapallindexed* Verification

When the *heapallindexed* argument to B-Tree verification functions is `true`, an additional phase of verification is performed against the table associated with the target index relation. This consists of a “dummy” `CREATE INDEX` operation, which checks for the presence of all hypothetical new index tuples against a temporary, in-memory summarizing structure (this is built when needed during the basic first phase of verification). The summarizing structure “fingerprints” every tuple found within the target index. The high level principle behind *heapallindexed* verification is that a new index that is equivalent to the existing, target index must only have entries that can be found in the existing structure.

The additional *heapallindexed* phase adds significant overhead: verification will typically take several times longer. However, there is no change to the relation-level locks acquired when *heapallindexed* verification is performed.

The summarizing structure is bound in size by *maintenance\_work\_mem*. In order to ensure that there is no more than a 2% probability of failure to detect an inconsistency for each heap tuple that should be represented in the index, approximately 2 bytes of memory are needed per tuple. As less memory is made available per tuple, the probability of missing an inconsistency slowly increases. This approach limits the overhead of verification significantly, while only slightly reducing the probability of detecting a problem, especially for installations where verification is treated as a routine maintenance task. Any single absent or malformed tuple has a new opportunity to be detected with each new verification attempt.

### F.2.3. Using *amcheck* Effectively

*amcheck* can be effective at detecting various types of failure modes that [data checksums](#) will fail to catch. These include:

- Structural inconsistencies caused by incorrect operator class implementations.

This includes issues caused by the comparison rules of operating system collations changing. Comparisons of datums of a collatable type like *text* must be immutable (just as all comparisons used for B-Tree index scans must be immutable), which implies that operating system collation rules must never change. Though rare, updates to operating system collation rules can cause these issues. More commonly, an inconsistency in the collation order between a primary server and a standby server is implicated, possibly because the *major* operating system version in use is inconsistent. Such inconsistencies will generally only arise on standby servers, and so can generally only be detected on standby servers.

If a problem like this arises, it may not affect each individual index that is ordered using an affected collation, simply because *indexed* values might happen to have the same absolute ordering regardless of the behavioral inconsistency. See [Section 23.1](#) and [Section 23.2](#) for further details about how Postgres Pro uses operating system locales and collations.

- Structural inconsistencies between indexes and the heap relations that are indexed (when *heapallindexed* verification is performed).

There is no cross-checking of indexes against their heap relation during normal operation. Symptoms of heap corruption can be subtle.

- Corruption caused by hypothetical undiscovered bugs in the underlying Postgres Pro access method code, sort code, or transaction management code.

Automatic verification of the structural integrity of indexes plays a role in the general testing of new or proposed Postgres Pro features that could plausibly allow a logical inconsistency to be introduced. Verification of table structure and associated visibility and transaction status information plays a similar role. One obvious testing strategy is to call *amcheck* functions continuously when running the standard regression tests.

- File system or storage subsystem faults where checksums happen to simply not be enabled.

Note that *amcheck* examines a page as represented in some shared memory buffer at the time of verification if there is only a shared buffer hit when accessing the block. Consequently, *amcheck* does not necessarily examine data read from the file system at the time of verification. Note that when checksums are enabled, *amcheck* may raise an error due to a checksum failure when a corrupt block is read into a buffer.

- Corruption caused by faulty RAM, or the broader memory subsystem.

Postgres Pro does not protect against correctable memory errors and it is assumed you will operate using RAM that uses industry standard Error Correcting Codes (ECC) or better protection. However, ECC memory is typically only immune to single-bit errors, and should not be assumed to provide *absolute* protection against failures that result in memory corruption.

When *heapallindexed* verification is performed, there is generally a greatly increased chance of detecting single-bit errors, since strict binary equality is tested, and the indexed attributes within the heap are tested.

Structural corruption can happen due to faulty storage hardware, or relation files being overwritten or modified by unrelated software. This kind of corruption can also be detected with [data page checksums](#).

Relation pages which are correctly formatted, internally consistent, and correct relative to their own internal checksums may still contain logical corruption. As such, this kind of corruption cannot be detected with checksums. Examples include toasted values in the main table which lack a corresponding entry in the toast table, and tuples in the main table with a Transaction ID that is older than the oldest valid Transaction ID in the database or cluster.

Multiple causes of logical corruption have been observed in production systems, including bugs in the PostgreSQL server software, faulty and ill-conceived backup and restore tools, and user error.

Corrupt relations are most concerning in live production environments, precisely the same environments where high risk activities are least welcome. For this reason, *verify\_heapam* has been designed to diagnose corruption without undue risk. It cannot guard against all causes of backend crashes, as even executing the calling query could be unsafe on a badly corrupted system. Access to [catalog tables](#) is performed and could be problematic if the catalogs themselves are corrupted.

In general, *amcheck* can only prove the presence of corruption; it cannot prove its absence.

## F.2.4. Repairing Corruption

No error concerning corruption raised by *amcheck* should ever be a false positive. *amcheck* raises errors in the event of conditions that, by definition, should never happen, and so careful analysis of *amcheck* errors is often required.

There is no general method of repairing problems that *amcheck* detects. An explanation for the root cause of an invariant violation should be sought. [pageinspect](#) may play a useful role in diagnosing corruption that *amcheck* detects. A *REINDEX* may not be effective in repairing corruption.

## F.3. *apache\_age*

*apache\_age* is a Postgres Pro extension that provides graph database functionality. AGE is an acronym for A Graph Extension. The goal of the project is to create single storage that can handle both relational and graph model data so that users can use standard ANSI SQL along with openCypher, the graph query language.

### Important

User tables in *apache\_age* databases contain columns using *reg\** OID-referencing system data types, therefore upgrading to a major version with [pg\\_upgrade](#) is not supported.

### F.3.1. Installation and Setup

The *apache\_age* extension is included into Postgres Pro Enterprise. Once you have Postgres Pro Enterprise installed, create the *apache\_age* extension:

```
CREATE EXTENSION age;
```

For every connection of *apache\_age* you start, load the *apache\_age* library.

```
LOAD 'age';
```

Non-superusers must specify the full path to load the *apache\_age* library.

```
LOAD '$libdir/plugins/age.so';
```

Add `ag_catalog` to the `search_path` to simplify queries:

```
SET search_path = ag_catalog, '$user', public;
```

In order to use `apache_age`, non-superusers need `USAGE` privileges on the `ag_catalog` schema (example for user `db_user`):

```
GRANT USAGE ON SCHEMA ag_catalog TO db_user;  
GRANT ALL PRIVILEGES ON ALL TABLES IN SCHEMA ag_catalog TO db_user;
```

## F.3.2. Graphs

A graph consists of a set of vertices and edges, where each individual node and edge possesses a map of properties. A vertex is the basic object of a graph, that can exist independently of everything else in the graph. An edge creates a directed connection between two vertices.

### F.3.2.1. Create a Graph

To create a graph, use the `create_graph` function, located in the `ag_catalog` namespace.

```
create_graph(graph_name text) returns void
```

This function will not return any results. The graph is created if there is no error message. Tables needed to set up the graph are created automatically.

```
SELECT * FROM ag_catalog.create_graph('graph_name');
```

### F.3.2.2. Grant Privileges

As a superuser, you can grant privilege on a specific existing graph to a non-superuser (example for graph `graph1` and user `db_user`):

```
GRANT USAGE ON SCHEMA graph1 TO db_user;  
GRANT ALL PRIVILEGES ON SCHEMA graph1 TO db_user;  
GRANT ALL PRIVILEGES ON ALL TABLES IN SCHEMA graph1 TO db_user;  
GRANT ALL PRIVILEGES ON TABLE graph1._ag_label_vertex TO db_user;
```

### F.3.2.3. Delete a Graph

To delete a graph, use the `drop_graph` function, located in the `ag_catalog` namespace.

```
drop_graph(graph_name text, cascade boolean) returns void
```

This function will not return any results. If there is no error message the graph has been deleted. It is recommended to set the `cascade` option to true, otherwise everything in the graph must be manually dropped with SQL DDL commands.

```
SELECT * FROM ag_catalog.drop_graph('graph_name', true);
```

### F.3.2.4. How Graphs Are Stored In Postgres Pro

When creating graphs with `apache_age`, a Postgres Pro namespace will be generated for every individual graph. The name and namespace of the created graphs can be seen within the `ag_graph` table from the `ag_catalog` namespace:

```
SELECT create_graph('new_graph');
```

```
NOTICE:  graph 'new_graph' has been created  
create_graph
```

```
-----
```

(1 row)

```
SELECT * FROM ag_catalog.ag_graph;
```

| name      | namespace |
|-----------|-----------|
| new_graph | new_graph |

(1 row)

After creating the graph, two tables are going to be created under the graph namespace to store vertices and edges: `_ag_label_vertex` and `_ag_label_edge`. These will be the parent tables of any new vertex or edge label. The query below shows how to retrieve the edge and vertex labels for all the graphs in the database.

```
-- Before creating a new vertex label.
```

```
SELECT * FROM ag_catalog.ag_label;
```

| name                    | graph | id | kind | relation                   | seq_name |
|-------------------------|-------|----|------|----------------------------|----------|
| _ag_label_vertex        | 68484 | 1  | v    | new_graph._ag_label_vertex |          |
| _ag_label_vertex_id_seq |       |    |      |                            |          |
| _ag_label_edge          | 68484 | 2  | e    | new_graph._ag_label_edge   |          |
| _ag_label_edge_id_seq   |       |    |      |                            |          |

(2 rows)

```
-- Creating a new vertex label.
```

```
SELECT create_vlabel('new_graph', 'Person');
```

```
NOTICE: VLabel 'Person' has been created
```

```
create_vlabel
```

(1 row)

```
-- After creating a new vertex label.
```

```
SELECT * FROM ag_catalog.ag_label;
```

| name                    | graph | id | kind | relation                   | seq_name      |
|-------------------------|-------|----|------|----------------------------|---------------|
| _ag_label_vertex        | 68484 | 1  | v    | new_graph._ag_label_vertex |               |
| _ag_label_vertex_id_seq |       |    |      |                            |               |
| _ag_label_edge          | 68484 | 2  | e    | new_graph._ag_label_edge   |               |
| _ag_label_edge_id_seq   |       |    |      |                            |               |
| Person                  | 68484 | 3  | v    | new_graph.'Person'         | Person_id_seq |

(3 rows)

Whenever a vertex label is created with the `create_vlabel()` function, a new table is generated within the `new_graph` namespace: `new_graph.'label'`. The same works for the `create_elabel()` function for the creation of edge labels. Creating vertices and edges with Cypher will automatically make these tables.

```
-- Creating two vertices and one edge.
```

```
SELECT * FROM cypher('new_graph', $$
CREATE (:Person {name: 'Daedalus'})-[:FATHER_OF]->(:Person {name: 'Icarus'})
$$) AS (a agtype);
```

```
a
---
```

(0 rows)

-- Showing the newly created tables.

```
SELECT * FROM ag_catalog.ag_label;
```

| name                    | graph | id | kind | relation                   | seq_name         |
|-------------------------|-------|----|------|----------------------------|------------------|
| _ag_label_vertex        | 68484 | 1  | v    | new_graph._ag_label_vertex |                  |
| _ag_label_vertex_id_seq |       |    |      |                            |                  |
| _ag_label_edge          | 68484 | 2  | e    | new_graph._ag_label_edge   |                  |
| _ag_label_edge_id_seq   |       |    |      |                            |                  |
| Person                  | 68484 | 3  | v    | new_graph.'Person'         | Person_id_seq    |
| FATHER_OF               | 68484 | 4  | e    | new_graph.'FATHER_OF'      | FATHER_OF_id_seq |

(4 rows)

### Note

It is recommended that no DML or DDL commands are executed in the namespace that is reserved for the graph.

## F.3.3. The apache\_age Cypher Query Format

Cypher queries are constructed using a function called `cypher` in `ag_catalog`, which returns a Postgres Pro [SETOF records](#).

`cypher(graph_name name, query_string cstring, parameters agtype)` returns `setof record`

Executes the Cypher query passed as an argument. If the Cypher query does not return results, a record definition still needs to be defined. The parameter map specified as `parameters` can only be used with [prepared statements](#). An error will be thrown otherwise.

```
SELECT * FROM cypher('graph_name', $$
/* Cypher Query Here */
$$) AS (result1 agtype, result2 agtype);
```

### F.3.3.1. Cypher in an Expression

Cypher may not be used as part of an expression, use a subquery instead. See [Advanced Cypher Queries](#) for information about how to use Cypher queries with expressions.

### F.3.3.2. SELECT Clause

Calling Cypher in the `SELECT` clause as an independent column is not allowed. However, Cypher may be used when it belongs as a conditional.

```
SELECT
    cypher('graph_name', $$
        MATCH (v:Person)
        RETURN v.name
    $$);
```

ERROR: cypher(...) in expressions is not supported

```
LINE 3:     cypher('graph_name', $$
           ^
```

HINT: Use subquery instead if possible.

## F.3.4. Data Types — Introduction to agtype

`apache_age` uses a custom data type called `agtype`, which is the only data type returned by `apache_age`. `agtype` is a superset of `json` and a custom implementation of `jsonb`.

### F.3.4.1. Simple Data Types

#### F.3.4.1.1. Null

In Cypher, `null` is used to represent missing or undefined values. Conceptually, `null` means “a missing unknown value”, and it is treated differently from other values. For example, getting a property from a vertex that does not have said property produces `null`. Most expressions that take `null` as input will produce `null`. This includes boolean expressions that are used as predicates in the `WHERE` clause. In this case, anything that is not true is interpreted as being false. `null` is not equal to `null`. Not knowing two values does not imply that they are the same value. So the expression `null = null` yields `null` and not `true`.

The following query returns `null` as an empty space.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN NULL
$$) AS (null_result agtype);
```

```
    null_result
-----
```

```
(1 row)
```

The concept of `NULL` in `agtype` and Postgres Pro is the same as it is in Cypher.

#### F.3.4.1.2. Integer

The `integer` type stores whole numbers, i.e. numbers without fractional components. Integer data type is a 64-bit field that stores values from -9,223,372,036,854,775,808 to 9,223,372,036,854,775,807. Attempts to store values outside this range will result in an error.

The type `integer` is the common choice, as it offers the best balance between range, storage size, and performance. The `smallint` type is generally used only if disk space is at a premium. The `bigint` type is designed to be used when the range of the integer type is insufficient.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN 1
$$) AS (int_result agtype);
```

```
    int_result
-----
```

```
1
```

```
(1 row)
```

#### F.3.4.1.3. Float

The data type `float` is an inexact, variable-precision numeric type, conforming to the IEEE 754 Standard.

Inexact means that some values cannot be converted exactly to the internal format and are stored as approximations, so that storing and retrieving a value might show slight discrepancies. Managing these errors and how they propagate through calculations is the subject of an entire branch of mathematics and computer science and will not be discussed here, except for the following points:

- If you require exact storage and calculations (such as for monetary amounts), use the `numeric` type instead.
- If you want to do complicated calculations with these types for anything important, especially if you rely on certain behavior in boundary cases (infinity, underflow), you should evaluate the implementation carefully.
- Comparing two floating-point values for equality might not always work as expected.

Values that are too large or too small will cause an error. Rounding might take place if the precision of an input number is too high. Numbers too close to zero that are not representable as distinct from zero will cause an underflow error.

In addition to ordinary numeric values, the floating-point types have several special values:

- Infinity
- -Infinity
- NaN

These represent the IEEE 754 special values “infinity”, “negative infinity”, and “not-a-number”, respectively. When writing these values as constants in a Cypher command, you must put quotes around them and typecast them, for example:

```
SET x.float_value = '-Infinity'::float
```

On input, these strings are recognized in a case-insensitive manner.

### Note

Note that IEEE 754 specifies that NaN should not compare equal to any other floating-point value (including NaN). However, in order to allow floats to be sorted correctly, `apache_age` evaluates `'NaN'::float = 'NaN'::float` to true. See [Comparability and Equality](#) for more details.

To use a float, denote a decimal value.

```
SELECT *  
FROM cypher('graph_name', $$  
    RETURN 1.0  
$$) AS (float_result agtype);
```

```
float_result  
-----  
1.0  
(1 row)
```

#### F.3.4.1.4. Numeric

The type `numeric` can store numbers with a very large number of digits. It is especially recommended for storing monetary amounts and other quantities where exactness is required. Calculations with `numeric` values yield exact results where possible, e.g., addition, subtraction, multiplication. However, calculations on `numeric` values are very slow compared to the integer types, or to the floating-point types.

We use the following terms below: The *precision* of a `numeric` is the total count of significant digits in the whole number, that is, the number of digits to both sides of the decimal point. The *scale* of a `numeric` is the count of decimal digits in the fractional part, to the right of the decimal point. So the number 23.5141 has a precision of 6 and a scale of 4. Integers can be considered to have a scale of zero.

Specifying `NUMERIC` without any precision or scale creates a column in which numeric values of any precision and scale can be stored, up to the implementation limit on precision. A column of this kind will not coerce input values to any particular scale, whereas `numeric` columns with a declared scale will coerce input values to that scale. (The SQL standard requires a default scale of 0, i.e., coercion to integer precision. We find this a bit useless. If you are concerned about portability, always specify the precision and scale explicitly.)

### Note

The maximum allowed precision when explicitly specified in the type declaration is 1000; `NUMERIC` without a specified precision is subject to the limits described in [Table 8.2](#).

If the scale of a value to be stored is greater than the declared scale of the column, the system will round the value to the specified number of fractional digits. Then, if the number of digits to the left of the decimal point exceeds the declared precision minus the declared scale, an error is raised.

Numeric values are physically stored without any extra leading or trailing zeroes. Thus, the declared precision and scale of a column are maximums, not fixed allocations. (In this sense the `numeric` type is more akin to `varchar(n)` than to `char(n)`.) The actual storage requirement is two bytes for each group of four decimal digits, plus three to eight bytes overhead.

In addition to ordinary numeric values, the `numeric` type allows the special value `NaN`, meaning “not-a-number”. Any operation on `NaN` yields another `NaN`. When writing this value as a constant in an SQL command, you must put quotes around it, for example `UPDATE table SET x = 'NaN'`. On input, the string `NaN` is recognized in a case-insensitive manner.

### Note

In most implementations of the “not-a-number” concept, `NaN` is not considered equal to any other numeric value (including `NaN`). However, in order to allow floats to be sorted correctly, `apache_age` evaluates `'NaN'::numeric = 'NaN':numeric` to true. See [Comparability and Equality](#) for more details.

When rounding values, the `numeric` type rounds ties away from zero, while (on most machines) the `real` and `double precision` types round ties to the nearest even number.

When creating a `numeric` data type, the `::numeric` data annotation is required.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN 1.0::numeric
$$) AS (numeric_result agtype);

numeric_result
-----
1.0::numeric
(1 row)
```

#### F.3.4.1.5. Bool

`apache_age` provides the standard Cypher type `boolean`. The `boolean` type can have several states: `true`, `false`, and a third state, `unknown`, which is represented by the `agtype null` value.

Boolean constants can be represented in Cypher queries by the keywords `TRUE`, `FALSE`, and `NULL`.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN TRUE
$$) AS (boolean_result agtype);

boolean_result
-----
true
(1 row)
```

Unlike Postgres Pro, in `apache_age` `boolean` outputs as the full word, i.e. `true` and `false` as opposed to `t` and `f`.

#### F.3.4.1.6. String

`agtype` string literals can contain the following escape sequences:

**Table F.2. Escape Sequences**

| Escape Sequence | Character                                               |
|-----------------|---------------------------------------------------------|
| \t              | Tab                                                     |
| \b              | Backspace                                               |
| \n              | Newline                                                 |
| \r              | Carriage Return                                         |
| \f              | Form Feed                                               |
| \'              | Single Quote                                            |
| \"              | Double Quote                                            |
| \\              | Backslash                                               |
| \uXXXX          | Unicode UTF-16 code point (4 hex digits must follow \u) |

Use single (') quotes to identify a string. The output will use double (") quotes.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN 'This is a string'
$$) AS (string_result agtype);

string_result
-----
"This is a string"
(1 row)
```

## F.3.4.2. Composite Data Types

### F.3.4.2.1. List

All examples will use the `WITH` clause and `RETURN` clause.

A literal list is created by using brackets and separating the elements in the list with commas.

```
SELECT *
FROM cypher('graph_name', $$
    WITH [0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10] as lst
    RETURN lst
$$) AS (lst agtype);

          lst
-----
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10]
(1 row)
```

A list can hold the value `null`, unlike when a `null` is an independent value, it will appear as the word `null` in a list.

```
SELECT *
FROM cypher('graph_name', $$
    WITH [null] as lst
    RETURN lst
$$) AS (lst agtype);

lst
-----
[null]
```

(1 row)

To access individual elements in the list, we use the square brackets again. This will extract from the start index and up to but not including the end index.

```
SELECT *
FROM cypher('graph_name', $$
    WITH [0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10] as lst
    RETURN lst[3]
$$) AS (element agtype);
```

```
element
-----
3
(1 row)
```

**Map elements in lists:**

```
SELECT *
FROM cypher('graph_name', $$
    WITH [0, {key: 'key_value'}, 2, 3, 4, 5, 6, 7, 8, 9, 10] as lst
    RETURN lst
$$) AS (map_value agtype);
```

```
map_value
-----
[0, {"key": "key_value"}, 2, 3, 4, 5, 6, 7, 8, 9, 10]
(1 row)
```

**Accessing map elements in lists:**

```
SELECT *
FROM cypher('graph_name', $$
    WITH [0, {key: 'key_value'}, 2, 3, 4, 5, 6, 7, 8, 9, 10] as lst
    RETURN lst[1].key
$$) AS (map_value agtype);
```

```
map_value
-----
"key_value"
(1 row)
```

You can also use negative numbers, to start from the end of the list instead.

```
SELECT *
FROM cypher('graph_name', $$
    WITH [0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10] as lst
    RETURN lst[-3]
$$) AS (element agtype);
```

```
element
-----
8
(1 row)
```

Finally, you can use ranges inside the brackets to return ranges of the list.

```
SELECT *
FROM cypher('graph_name', $$
    WITH [0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10] as lst
    RETURN lst[0..3]
$$) AS (element agtype);
```

```
    element
-----
 [0, 1, 2]
(1 row)
```

#### Negative index ranges:

```
SELECT *
FROM cypher('graph_name', $$
    WITH [0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10] as lst
    RETURN lst[0..-5]
$$) AS (lst agtype);
```

```
    lst
-----
 [0, 1, 2, 3, 4, 5]
(1 row)
```

#### Positive slices:

```
SELECT *
FROM cypher('graph_name', $$
    WITH [0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10] as lst
    RETURN lst[..4]
$$) AS (lst agtype);
```

```
    lst
-----
 [0, 1, 2, 3]
(1 row)
```

#### Negative slices:

```
SELECT *
FROM cypher('graph_name', $$
    WITH [0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10] as lst
    RETURN lst[-5..]
$$) AS (lst agtype);
```

```
    lst
-----
 [6, 7, 8, 9, 10]
(1 row)
```

Out-of-bound slices are simply truncated, but out-of-bound single elements return null.

```
SELECT *
FROM cypher('graph_name', $$
    WITH [0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10] as lst
    RETURN lst[15]
$$) AS (element agtype);
```

```
    element
-----
(1 row)
```

```
SELECT *
FROM cypher('graph_name', $$
    WITH [0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10] as lst
```

```
RETURN lst[5..15]
$$) AS (element agtype);

      element
-----
[5, 6, 7, 8, 9, 10]
(1 row)
```

#### F.3.4.2.2. Map

Maps can be constructed using Cypher.

You can construct a simple map with simple agtype values.

```
SELECT *
FROM cypher('graph_name', $$
    WITH {int_key: 1, float_key: 1.0, numeric_key: 1::numeric, bool_key: true,
    string_key: 'Value'} as m
    RETURN m
$$) AS (m agtype);

                                     m
-----
{"int_key": 1, "bool_key": true, "float_key": 1.0, "string_key": "Value",
"numeric_key": 1::numeric}
(1 row)
```

A map can also contain composite data types, i.e. lists and other maps.

```
SELECT *
FROM cypher('graph_name', $$
    WITH {listKey: [{inner: 'Map1'}], mapKey: {i: 0}} as m
    RETURN m
$$) AS (m agtype);

                                     m
-----
{"mapKey": {"i": 0}, "listKey": [{"inner": "Map1"}, {"inner": "Map2"}]}
(1 row)
```

Property access of a map:

```
SELECT *
FROM cypher('graph_name', $$
    WITH {int_key: 1, float_key: 1.0, numeric_key: 1::numeric, bool_key: true,
    string_key: 'Value'} as m
    RETURN m.int_key
$$) AS (int_key agtype);

      int_key
-----
1
(1 row)
```

Accessing list elements in maps:

```
SELECT *
FROM cypher('graph_name', $$
    WITH {listKey: [{inner: 'Map1'}], mapKey: {i: 0}} as m
    RETURN m.listKey[0]
$$) AS (m agtype);
```

```
-----m
{"inner": "Map1"}
(1 row)
```

### F.3.4.3. Simple Entities

An entity has a unique, comparable identity which defines whether or not two entities are equal.

An entity is assigned a set of properties, each of which are uniquely identified in the set by the respective property keys.

#### F.3.4.3.1. Graph ID

Simple entities are assigned a unique `graphid`. A `graphid` is a unique composition of the entity label id and a unique sequence assigned to each label. Note that there will be overlap in IDs when comparing entities from different graphs.

A label is an identifier that classifies vertices and edges into certain categories.

- Edges are required to have a label, but vertices do not.
- The names of labels between vertices and edges cannot overlap.

See [CREATE](#) clause for information about how to make entities with labels.

Both vertices and edges may have properties. Properties are attribute values, and each attribute name should be defined only as a string type.

#### F.3.4.4. Vertex

- A vertex is the basic entity of the graph, with the unique attribute of being able to exist in and of itself.
- A vertex may be assigned a label.
- A vertex may have zero or more outgoing edges.
- A vertex may have zero or more incoming edges.

**Table F.3. Data Format**

| Attribute Name | Description                            |
|----------------|----------------------------------------|
| id             | Graph ID for this vertex               |
| label          | Name of the label this vertex has      |
| properties     | Properties associated with this vertex |

```
{id:1; label: 'label_name'; properties: {prop1: value1, prop2: value2}}::vertex
```

Type casting a map to a vertex:

```
SELECT *
FROM cypher('graph_name', $$
    WITH {id: 0, label: 'label_name', properties: {i: 0}}::vertex as v
    RETURN v
$$) AS (v agtype);
```

```
-----v
{"id": 0, "label": "label_name", "properties": {"i": 0}}::vertex
(1 row)
```

#### F.3.4.5. Edge

An edge is an entity that encodes a directed connection between exactly two nodes, the source node and the target node. An outgoing edge is a directed relationship from the point of view of its source

node. An incoming edge is a directed relationship from the point of view of its target node. An edge is assigned exactly one edge type.

**Table F.4. Data Format**

| Attribute Name | Description                            |
|----------------|----------------------------------------|
| id             | Graph ID for this edge                 |
| startid        | Graph ID for the source node           |
| endid          | Graph ID for the target node           |
| label          | Name of the label this vertex has      |
| properties     | Properties associated with this vertex |

```
{id: 3; startid: 1; endid: 2; label: 'edge_label' properties{prop1: value1, prop2: value2}}::edge
```

Type casting a map to an edge:

```
SELECT *
FROM cypher('graph_name', $$
    WITH {id: 2, start_id: 0, end_id: 1, label: 'label_name', properties: {i: 0}}::edge
    as e
    RETURN e
$$) AS (e agtype);
```

e

```
-----
{"id": 2, "label": "label_name", "end_id": 1, "start_id": 0, "properties": {"i":
0}}::edge
(1 row)
```

### F.3.4.6. Composite Entities

A path is a series of alternating vertices and edges. A path must start with a vertex, and have at least one edge.

Type casting a list to a path:

```
SELECT *
FROM cypher('graph_name', $$
    WITH [{id: 0, label: 'label_name_1', properties: {i: 0}}::vertex,
        {id: 2, start_id: 0, end_id: 1, label: 'edge_label', properties: {i:
0}}::edge,
        {id: 1, label: 'label_name_2', properties: {}}::vertex
    ]::path as p
    RETURN p
$$) AS (p agtype);
```

p

```
-----
[{"id": 0, "label": "label_name_1", "properties": {"i": 0}}::vertex, {"id": 2,
"label": "edge_label", "end_id": 1, "start_id": 0, "properties": {"i": 0}}::edge,
{"id": 1, "label": "label_name_2", "properties": {}}::vertex]::path
(1 row)
```

### F.3.5. Comparability, Equality, Orderability and Equivalence

apache\_age already has good semantics for equality within the primitive types (booleans, strings, integers, and floats) and maps. Furthermore, Cypher has good semantics for comparability and orderability

for integers, floats, and strings, within each of the types. However, working with values of different types deviates from Postgres Pro defined logic and the openCypher specification:

- Comparability between values of different types is defined. This deviation is particularly pronounced when it occurs as part of the evaluation of predicates (in `WHERE`).
- `ORDER BY` will not fail if the values passed to it have different types.

The underlying conceptual model is complex and sometimes inconsistent. This leads to an unclear relationship between comparison operators, equality, grouping, and `ORDER BY`. Comparability and orderability are aligned with each other consistently, as all types can be ordered and compared. The difference between equality and equivalence, as exposed by `IN`, `=`, `DISTINCT`, and grouping, in `apache_age` is limited to testing two instances of the value `null` to each other. In equality, `null = null` is `null`. In equivalence, used by `DISTINCT` and when grouping values, two `null` values are always treated as being the same value. However, equality treats `null` values differently if they are an element of a list or a map value.

### F.3.5.1. Concepts

The openCypher specification features four distinct concepts related to equality and ordering:

- Comparability is used by the inequality operators (`>`, `<`, `>=`, `<=`) and defines the underlying semantics of how to compare two values.
- Equality is used by the equality operators (`=`, `<>`), and the list membership operator (`IN`). It defines the underlying semantics to determine if two values are the same in these contexts. Equality is also used implicitly by literal maps in node and relationship patterns, since such literal maps are merely a shorthand notation for equality predicates.
- Orderability is used by the `ORDER BY` clause, and defines the underlying semantics of how to order values.
- Equivalence is used by the `DISTINCT` modifier and by grouping in projection clauses (`WITH`, `RETURN`), and defines the underlying semantics to determine if two values are the same in these contexts.

### F.3.5.2. Comparability and Equality

Comparison operators need to function as one would expect comparison operators to function — equality and comparability. But, at the same time, they need to allow the sorting of column data — equivalence and orderability.

Unfortunately, it may not be possible to implement separate comparison operators for equality and comparison operations, and, equivalence and orderability operations, in Postgres Pro, for the same query. So we prioritize equivalence and orderability over equality and comparability to allow for ordering of output data.

#### F.3.5.2.1. Comparability

Comparability is defined between any pair of values, as specified below.

- Numbers
  - Numbers of different types (excluding NaN values and the Infinities) are compared to each other as if both numbers would have been coerced to arbitrary precision `bigdecimal` (currently outside the Cypher type system) before comparing them with each other numerically in ascending order.
  - Comparison to any value that is not also number follows the rules of orderability.
  - Floats do not have the required precision to represent all of the whole numbers in the range of `agtype integer` and `agtype numeric`. When casting an `integer` or `agtype numeric` to a float, unexpected results can occur when casting values in the high and low range.
- Integers
  - Integers are compared numerically in ascending order.
- Floats
  - Floats (excluding NaN values and the Infinities) are compared numerically in ascending order.

- Positive infinity is of type `FLOAT`, equal to itself and greater than any other number, except NaN values.
- Negative infinity is of type `FLOAT`, equal to itself and less than any other number.
- NaN values are comparable to each and greater than any other float value.
- Numeric
  - Numerics are compared numerically in ascending order.
- Booleans
  - Booleans are compared such that false is less than true.
  - Comparison to any value that is not also a boolean follows the rules of orderability.
- Strings
  - Strings are compared in dictionary order, i.e. characters are compared pairwise in ascending order from the start of the string to the end. Characters missing in a shorter string are considered to be less than any other character. For example, `'a' < 'aa'`.
  - Comparison to any value that is not also a string follows the rules of orderability.
- Lists
  - Lists are compared in sequential order, i.e. list elements are compared pairwise in ascending order from the start of the list to the end. Elements missing in a shorter list are considered to be less than any other value (including `null` values), for example, `[1] < [1, 0]` but also `[1] < [1, null]`.
  - Comparison to any value that is not also a list follows the rules of orderability.
- Maps
  - The comparison order for maps is unspecified and left to implementations.
  - The comparison order for maps must align with the equality semantics outlined below. In consequence, any map that contains an entry that maps its key to a null value is incomparable. For example, `{a: 1} <= {a: 1, b: null}` evaluates to null.
  - Comparison to any value that is not also a regular map follows the rules of orderability.

#### Entities:

- Vertices: The comparison order for vertices is based on the assigned `graphid`.
- Edges: The comparison order for edges is based on the assigned `graphid`.
- Paths: Paths are compared as if they were a list of alternating nodes and relationships of the path from the start node to the end node. For example, given nodes `n1`, `n2`, `n3`, and relationships `r1` and `r2`, and given that `n1 < n2 < n3` and `r1 < r2`, then the path `p1` from `n1` to `n3` via `r1` would be less than the path `p2` to `n1` from `n2` via `r2`. Paths are expressed in terms of lists:

```
p1 < p2
<=> [n1, r1, n3] < [n1, r2, n2]
<=> n1 < n1 || (n1 = n1 && [r1, n3] < [r2, n2])
<=> false || (true && [r1, n3] < [r2, n2]) <=> [r1, n3] < [r2, n2]
<=> r1 < r2 || (r1 = r2 && n3 < n2)
<=> true || (false && false)
<=> true
```

### Note

Comparison to any value that is not also a path will return false.

- NULL: `null` is incomparable with any other value (including other `null` values.)

### F.3.5.3. Orderability Between Different `agtype` Types

The ordering of different `agtype` types, when using `<`, `<=`, `>`, `>=` from the smallest value to the largest value is:

1. Path
2. Edge
3. Vertex
4. Object
5. Array
6. String
7. Bool
8. Numeric, Integer, Float
9. NULL

## Note

This is subject to change in future releases.

## F.3.6. Operators

### F.3.6.1. String Specific Comparison Operators

```
SELECT * FROM cypher('graph_name', $$  
CREATE (:Person {name: 'John'}),  
       (:Person {name: 'Jeff'}),  
       (:Person {name: 'Joan'}),  
       (:Person {name: 'Bill'})  
$$) AS (result agtype);
```

#### Starts With

Performs case-sensitive prefix searching on strings.

```
SELECT * FROM cypher('graph_name', $$  
MATCH (v:Person)  
WHERE v.name STARTS WITH "J"  
RETURN v.name  
$$) AS (names agtype);
```

```
names  
-----  
"John"  
"Jeff"  
"Joan"  
(3 rows)
```

#### Contains

Performs case-sensitive inclusion searching in strings.

```
SELECT * FROM cypher('graph_name', $$  
MATCH (v:Person)  
WHERE v.name CONTAINS "o"  
RETURN v.name  
$$) AS (names agtype);
```

```
names  
-----  
"John"  
"Joan"  
(2 rows)
```

#### Ends With

Performs case-sensitive suffix searching on strings.

```
SELECT * FROM cypher('graph_name', $$  
  MATCH (v:Person)  
  WHERE v.name ENDS WITH "n"  
  RETURN v.name  
$$) AS (names agtype);
```

```
names  
-----  
"John"  
"Joan"  
(2 rows)
```

#### F.3.6.1.1. Regular Expressions

apache\_age supports the use of [POSIX regular expressions](#) using the `=~` operator. By default `=~` is case sensitive.

##### Basic String Matching

The `=~` operator when no special characters are given, act like the `=` operator.

```
SELECT * FROM cypher('graph_name', $$  
  MATCH (v:Person)  
  WHERE v.name =~ 'John'  
  RETURN v.name  
$$) AS (names agtype);
```

```
names  
-----  
"John"  
(1 row)
```

##### Case-Insensitive Search

Adding `(?i)` at the beginning of the string will make the comparison case insensitive.

```
SELECT * FROM cypher('graph_name', $$  
  MATCH (v:Person)  
  WHERE v.name =~ '(?i)JoHn'  
  RETURN v.name  
$$) AS (names agtype);
```

```
names  
-----  
"John"  
(1 row)
```

##### The . Wildcard

The `.` operator acts as a wildcard to match any single character.

```
SELECT * FROM cypher('graph_name', $$  
  MATCH (v:Person)  
  WHERE v.name =~ 'Jo.n'  
  RETURN v.name  
$$) AS (names agtype);
```

```
names  
-----  
"John"  
"Joan"
```

(2 rows)

### The \* Wildcard

The \* wildcard after a character will match to 0 or more of the previous character.

```
SELECT * FROM cypher('graph_name', $$  
  MATCH (v:Person)  
  WHERE v.name =~ 'Johz*n'  
  RETURN v.name  
$$) AS (names agtype);
```

```
names  
-----  
"John"  
(1 row)
```

### The + Operator

The + operator matches to 1 or more the previous character.

```
SELECT * FROM cypher('graph_name', $$  
  MATCH (v:Person)  
  WHERE v.name =~ 'Bil+'  
  RETURN v.name  
$$) AS (names agtype);
```

```
names  
-----  
"Bill"  
(1 row)
```

### The . and \* Wildcards Together

You can use the . and \* wildcards together to represent the rest of the string.

```
SELECT * FROM cypher('graph_name', $$  
  MATCH (v:Person)  
  WHERE v.name =~ 'J.*'  
  RETURN v.name  
$$) AS (names agtype);
```

```
names  
-----  
"John"  
"Jeff"  
"Joan"  
(3 rows)
```

## F.3.6.2. Operator Precedence

Operator precedence in apache\_age is shown below:

**Table F.5. Operator Precedence**

| Precedence | Operator    | Description                                |
|------------|-------------|--------------------------------------------|
| 1          | .           | Property Access                            |
| 2          | []          | Map and List Subscripting                  |
|            | ()          | Function Call                              |
| 3          | STARTS WITH | Case-sensitive prefix searching on strings |

| Precedence | Operator    | Description                                   |
|------------|-------------|-----------------------------------------------|
|            | ENDS WITH   | Case-sensitive suffix searching on strings    |
|            | CONTAINS    | Case-sensitive inclusion searching on strings |
|            | =~          | Regular expression string matching            |
| 4          | -           | Unary Minus                                   |
| 5          | IN          | Checking if an element exists in a list       |
|            | IS NULL     | Checking a value is NULL                      |
|            | IS NOT NULL | Checking a value is not NULL                  |
| 6          | ^           | Exponentiation                                |
| 7          | * / %       | Multiplication, division and remainder        |
| 8          | + -         | Addition and Subtraction                      |
| 9          | = <>        | For relational = and ≠ respectively           |
|            | < <=        | For relational < and ≤ respectively           |
|            | > >=        | For relational > and ≥ respectively           |
| 10         | NOT         | Logical NOT                                   |
| 11         | AND         | Logical AND                                   |
| 12         | OR          | Logical OR                                    |

### F.3.7. Aggregation

Generally an aggregation `aggr(expr)` processes all matching rows for each aggregation key found in an incoming record (keys are compared using [equivalence](#)).

In a regular aggregation (i.e. of the form `aggr(expr)`), the list of aggregated values is the list of candidate values with all `null` values removed from it.

```
SELECT * FROM cypher('graph_name', $$
    CREATE (a:Person {name: 'A', age: 13}),
    (b:Person {name: 'B', age: 33, eyes: "blue"}),
    (c:Person {name: 'C', age: 44, eyes: "blue"}),
    (d1:Person {name: 'D', eyes: "brown"}),
    (d2:Person {name: 'D'}),
    (a)-[:KNOWS]->(b),
    (a)-[:KNOWS]->(c),
    (a)-[:KNOWS]->(d1),
    (b)-[:KNOWS]->(d2),
    (c)-[:KNOWS]->(d2)
    $$) as (a agtype);
```

#### F.3.7.1. Auto Group By

To calculate aggregated data, Cypher offers aggregation, analogous to SQL `GROUP BY`.

Aggregating functions take a set of values and calculate an aggregated value over them. Examples are `avg()` that calculates the average of multiple numeric values, or `min()` that finds the smallest numeric

or string value in a set of values. When we say below that an aggregating function operates on a set of values, we mean these to be the result of the application of the inner expression (such as `n.age`) to all the records within the same aggregation group.

Aggregation can be computed over all the matching subgraphs, or it can be further divided by introducing grouping keys. These are non-aggregate expressions, that are used to group the values going into the aggregate functions.

Assume we have the following `RETURN` statement:

```
SELECT * FROM cypher('graph_name', $$  
    MATCH (v:Person)  
    RETURN v.name, count(*)  
$$) as (grouping_key agtype, count agtype);
```

| grouping_key | count |
|--------------|-------|
| "A"          | 1     |
| "D"          | 2     |
| "B"          | 1     |
| "C"          | 1     |

(4 rows)

We have two return expressions: `grouping_key`, and `count(*)`. The first, `grouping_key`, is not an aggregate function, and so it will be the grouping key. The latter, `count(*)` is an aggregate expression. The matching subgraphs will be divided into different buckets, depending on the grouping key. The aggregate function will then be run on these buckets, calculating an aggregate value per bucket.

### F.3.7.2. Sorting on Aggregate Functions

To use aggregations to sort the result set, the aggregation must be included in the `RETURN` to be used in the `ORDER BY`.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (me:Person)-[]->(friend:Person)  
    RETURN count(friend), me  
    ORDER BY count(friend)  
$$) as (friends agtype, me agtype);
```

### F.3.7.3. Distinct aggregation

In a distinct aggregation (i.e. of the form `aggr(DISTINCT expr)`), the list of aggregated values is the list of candidate values with all `null` values removed from it. Furthermore, in a distinct aggregation, only one of all equivalent candidate values is included in the list of aggregated values, i.e. duplicates under equivalence are removed.

The `DISTINCT` operator works in conjunction with aggregation. It is used to make all values unique before running them through an aggregate function.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (v:Person)  
    RETURN count(DISTINCT v.eyes), count(v.eyes)  
$$) as (distinct_eyes agtype, eyes agtype);
```

| distinct_eyes | eyes |
|---------------|------|
| 2             | 3    |

(1 row)

### F.3.7.4. Ambiguous Grouping Statements

This feature of not requiring the user to specify their grouping keys for a query allows for ambiguity on what Cypher should qualify as their grouping keys.

```
SELECT * FROM cypher('graph_name', $$
CREATE (:L {a: 1, b: 2, c: 3}),
       (:L {a: 2, b: 3, c: 1}),
       (:L {a: 3, b: 1, c: 2})
$$) as (a agtype);
```

#### F.3.7.4.1. Invalid Query in `apache_age`

`apache_age` solution to this problem is to not allow a `WITH` or `RETURN` column to combine aggregate functions with variables that are not explicitly listed in another column of the same `WITH` or `RETURN` clause.

```
SELECT * FROM cypher('graph_name', $$
MATCH (x:L)
RETURN x.a + count(*) + x.b + count(*) + x.c
$$) as (a agtype);
```

```
ERROR:  'x' must be either part of an explicitly listed key or used inside an aggregate
function
LINE 3: RETURN x.a + count(*) + x.b + count(*) + x.c
```

#### F.3.7.4.2. Valid Query in `apache_age`

Columns that do not include an aggregate function in `apache_age` are considered to be the grouping keys for that `WITH` or `RETURN` clause.

For the above query, the user could rewrite the query in several ways that will return results.

```
SELECT * FROM cypher('graph_name', $$
MATCH (x:L)
RETURN (x.a + x.b + x.c) + count(*) + count(*), x.a + x.b + x.c
$$) as (count agtype, key agtype);
```

| count | key |
|-------|-----|
| 12    | 6   |

(1 row)

`x.a + x.b + x.c` is the grouping key. Grouping keys created like this must include parenthesis.

```
SELECT * FROM cypher('graph_name', $$
MATCH (x:L)
RETURN x.a + count(*) + x.b + count(*) + x.c, x.a, x.b, x.c
$$) as (count agtype, a agtype, b agtype, c agtype);
```

| count | a | b | c |
|-------|---|---|---|
| 10    | 3 | 1 | 2 |
| 10    | 2 | 3 | 1 |
| 10    | 1 | 2 | 3 |

(3 rows)

`x.a`, `x.b`, and `x.c` will be considered different grouping keys.

#### F.3.7.4.3. Vertices and Edges in Ambiguous Grouping

Alternatively, the grouping key can be a vertex or edge, and then any properties of the vertex or edge can be specified without being explicitly stated in a `WITH` or `RETURN` column.

```
SELECT * FROM cypher('graph_name', $$  
    MATCH (x:L)  
    RETURN count(*) + count(*) + x.a + x.b + x.c, x  
$$) as (count agtype, key agtype);
```

| count | key                                                                                        |
|-------|--------------------------------------------------------------------------------------------|
| 8     | { "id": 1407374883553283, "label": "L", "properties": { "a": 3, "b": 1, "c": 2 } }::vertex |
| 8     | { "id": 1407374883553281, "label": "L", "properties": { "a": 1, "b": 2, "c": 3 } }::vertex |
| 8     | { "id": 1407374883553282, "label": "L", "properties": { "a": 2, "b": 3, "c": 1 } }::vertex |

(3 rows)

Results will be grouped on `x`, because it is safe to assume that properties considered unnecessary for grouping are unambiguous.

#### F.3.7.4.4. Hiding Unwanted Grouping Keys

If the grouping key is considered unnecessary for the query output, the aggregation can be done in a `WITH` clause then passing information to the `RETURN` clause.

```
SELECT * FROM cypher('graph_name', $$  
    MATCH (x:L)  
    WITH count(*) + count(*) + x.a + x.b + x.c as column, x  
    RETURN column  
$$) as (a agtype);
```

```
a  
---  
8  
8  
8  
(3 rows)
```

### F.3.8. Importing Graph from Files

You can use the following instructions to create a graph from the files:

- [Functions](#) to load graphs from files
- [Structure](#) of CSV files that load functions as input
- Simple source code [example](#) to load countries and cities from the files

#### Note

User must create graph and labels before loading data from files.

#### F.3.8.1. Load Graph Functions

Following are the details about the functions to create vertices and edges from the file.

Function `load_labels_from_file` is used to load vertices from CSV files.

```
load_labels_from_file('graph_name',  
                      'label_name',  
                      'file_path')
```

By adding the fourth parameter user can exclude the `id` field. Use this when there is no `id` field in the file.

```
load_labels_from_file('graph_name',  
                     'label_name',  
                     'file_path',  
                     false)
```

Function `load_edges_from_file` can be used to load edges from the CSV file. See the file structure below.

### Note

Make sure that IDs in the edge file are identical to ones that are in vertices files.

```
load_edges_from_file('graph_name',  
                    'label_name',  
                    'file_path');
```

## F.3.8.2. Explanation about the CSV format

Following is the explanation about the structure for CSV files for vertices and edges.

A CSV file for nodes is formatted as follows:

**Table F.6. CSV File Format for Nodes**

| Field name | Field description                                                                                                                                                                                                                  |
|------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| id         | The first column of the file. All values are a positive integer. This is an optional field when <code>id_field_exists</code> is false. However, it should be present when <code>id_field_exists</code> is <i>not</i> set to false. |
| Properties | All other columns contain the properties for the nodes. Header row contains the name of property.                                                                                                                                  |

Similarly, a CSV file for edges is formatted as follows:

**Table F.7. CSV File Format for Edges**

| Field name        | Field description                                                                                      |
|-------------------|--------------------------------------------------------------------------------------------------------|
| start_id          | Node ID of the node from where the edge is started. This ID is present in <code>nodes.csv</code> file. |
| start_vertex_type | Class of the node                                                                                      |
| end_id            | End ID of the node at which the edge is terminated.                                                    |
| end_vertex_type   | Class of the node                                                                                      |
| properties        | Properties of the edge. The header contains the property name.                                         |

## F.3.8.3. Example SQL Script

- Load `apache_age` and create a graph.

```
LOAD 'age';  
  
SET search_path TO ag_catalog;
```

```
SELECT create_graph('agload_test_graph');
```

- Create label `Country` and load vertices from the CSV file. Note that this CSV file has the `id` field.

```
SELECT create_vlabel('agload_test_graph', 'Country');
SELECT load_labels_from_file('agload_test_graph',
                             'Country',
                             '/age/regress/age_load/data/countries.csv');
```

- Create label `City` and load vertices from the CSV file. Note that this CSV file has the `id` field.

```
SELECT create_vlabel('agload_test_graph', 'City');
SELECT load_labels_from_file('agload_test_graph',
                             'City',
                             '/age/regress/age_load/data/cities.csv');
```

- Create label `has_city` and load edges from the CSV file.

```
SELECT create_elabel('agload_test_graph', 'has_city');
SELECT load_edges_from_file('agload_test_graph', 'has_city',
                            '/age/regress/age_load/data/edges.csv');
```

- Check if the graph has been loaded properly.

```
SELECT table_catalog, table_schema, table_name, table_type
FROM information_schema.tables
WHERE table_schema = 'agload_test_graph';
```

```
SELECT COUNT(*) FROM agload_test_graph."Country";
SELECT COUNT(*) FROM agload_test_graph."City";
SELECT COUNT(*) FROM agload_test_graph."has_city";
```

```
SELECT COUNT(*) FROM cypher('agload_test_graph', $$MATCH(n) RETURN n$$) as (n
agtype);
SELECT COUNT(*) FROM cypher('agload_test_graph', $$MATCH (a)-[e]->(b) RETURN e$$) as
(n agtype);
```

#### F.3.8.3.1. Creating Vertices Without ID Field in the File

- Create label `Country2` and load vertices from the CSV file. Note that this CSV file has no `id` field.

```
SELECT create_vlabel('agload_test_graph', 'Country2');
SELECT load_labels_from_file('agload_test_graph',
                             'Country2',
                             '/age/regress/age_load/data/countries.csv',
                             false);
```

- Create label `City2` and load vertices from CSV file. Note this CSV file has no `id` field.

```
SELECT create_vlabel('agload_test_graph', 'City2');
SELECT load_labels_from_file('agload_test_graph',
                             'City2',
                             '/age/regress/age_load/data/cities.csv',
                             false);
```

- Check if the graph has been loaded properly and perform difference analysis between IDs created automatically and picked from the files.

Labels `Country` and `City` were created with the `id` field in the file.

Labels `Country2` and `City2` were created with no `id` field in the file.

```
SELECT COUNT(*) FROM agload_test_graph."Country2";
SELECT COUNT(*) FROM agload_test_graph."City2";

SELECT id FROM agload_test_graph."Country" LIMIT 10;
```

```
SELECT id FROM agload_test_graph."Country2" LIMIT 10;

SELECT * FROM cypher('agload_test_graph', $$MATCH(n:Country {iso2 : 'BE'})
  RETURN id(n), n.name, n.iso2 $$) as ('id(n)' agtype, 'n.name' agtype, 'n.iso2'
  agtype);
SELECT * FROM cypher('agload_test_graph', $$MATCH(n:Country2 {iso2 : 'BE'})
  RETURN id(n), n.name, n.iso2 $$) as ('id(n)' agtype, 'n.name' agtype, 'n.iso2'
  agtype);

SELECT * FROM cypher('agload_test_graph', $$MATCH(n:Country {iso2 : 'AT'})
  RETURN id(n), n.name, n.iso2 $$) as ('id(n)' agtype, 'n.name' agtype, 'n.iso2'
  agtype);
SELECT * FROM cypher('agload_test_graph', $$MATCH(n:Country2 {iso2 : 'AT'})
  RETURN id(n), n.name, n.iso2 $$) as ('id(n)' agtype, 'n.name' agtype, 'n.iso2'
  agtype);

SELECT drop_graph('agload_test_graph', true);
```

## F.3.9. MATCH

The **MATCH** clause allows you to specify the patterns a query will search for in the database. This is the primary way of retrieving data for use in a query.

A **WHERE** clause often follows a **MATCH** clause to add user-defined restrictions to the matched patterns to manipulate the set of data returned. The predicates are part of the pattern description, and should not be considered a filter applied only after the matching is done. This means that **WHERE** should always be put together with the **MATCH** clause it belongs to.

**MATCH** can occur at the beginning of the query or later, possibly after a **WITH**. If it is the first clause, nothing will have been bound yet, and Cypher will design a search to find the results matching the clause and any associated predicates specified in any **WHERE** clause. Vertices and edges found by this search are available as bound pattern elements and can be used for pattern matching of sub-graphs. They can also be used in any future clauses where Cypher will use the known elements, and from there find further unknown elements.

Cypher is a declarative language, and so typically the query itself does not specify the algorithm to use to perform the search. Predicates in **WHERE** parts can be evaluated before pattern matching, during pattern matching, or after the match is found.

### F.3.9.1. Basic Vertex Finding

#### F.3.9.1.1. Get All Vertices

By specifying a pattern with a single vertex and no labels, all vertices in the graph will be returned.

```
SELECT * FROM cypher('graph_name', $$
MATCH (v)
RETURN v
$$) as (v agtype);
```

v

---

```
{id: 0; label: 'Person'; properties: {name: 'Charlie Sheen'}}::vertex
{id: 1; label: 'Person'; properties: {name: 'Martin Sheen'}}::vertex
{id: 2; label: 'Person'; properties: {name: 'Michael Douglas'}}::vertex
{id: 3; label: 'Person'; properties: {name: 'Oliver Stone'}}::vertex
{id: 4; label: 'Person'; properties: {name: 'Rob Reiner'}}::vertex
{id: 5; label: 'Movie'; properties: {name: 'Wall Street'}}::vertex
{id: 6; label: 'Movie'; properties: {title: 'The American President'}}::vertex
```

(7 rows)

Returns all vertices in the database.

#### F.3.9.1.2. Get All Vertices with a Label

Getting all vertices with a label is done with a single node pattern where the vertex has the label specified as follows:

```
SELECT * FROM cypher('graph_name', $$  
MATCH (movie:Movie)  
RETURN movie.title  
$$) as (title agtype);
```

```
          title  
-----  
'Wall Street'  
'The American President'  
(2 rows)
```

Returns all the movies in the database.

#### F.3.9.1.3. Related Vertices

The symbol `-[]-` specifies an edge, without specifying the type or direction of the edge.

```
SELECT * FROM cypher('graph_name', $$  
MATCH (director {name: 'Oliver Stone'})-[]-(movie)  
RETURN movie.title  
$$) as (title agtype);
```

```
          title  
-----  
'Wall Street'  
(1 row)
```

Returns all the movies directed by “Oliver Stone”.

#### F.3.9.1.4. Match with Labels

To constrain your pattern with labels on vertices, add it to the vertex in the pattern, using the label syntax.

```
SELECT * FROM cypher('graph_name', $$  
MATCH (:Person {name: 'Oliver Stone'})-[]-(movie:Movie)  
RETURN movie.title  
$$) as (title agtype);
```

```
          title  
-----  
'Wall Street'  
(1 row)
```

Returns any vertices connected with the `Person` “Oliver” that are labeled `Movie`.

### F.3.9.2. Edge Basics

#### F.3.9.2.1. Outgoing Edges

To return directed edges, you may use `->` or `<-` to specify the direction of which the edge points.

```
SELECT * FROM cypher('graph_name', $$  
MATCH (:Person {name: 'Oliver Stone'})-[]->(movie)
```

```
RETURN movie.title
$$) as (title agtype);
```

```
title
-----
'Wall Street'
(1 row)
```

Returns any vertices connected with the `Person` “Oliver” by an outgoing edge.

#### F.3.9.2.2. Directed Edges and Variable

If a variable is required, either for filtering on properties of the edge, or to return the edge, specify the variable within the edge or vertex you wish to use.

```
SELECT * FROM cypher('graph_name', $$
MATCH (:Person {name: 'Oliver Stone'})-[r]->(movie)
RETURN type(r)
$$) as (title agtype);
```

```
title
-----
'DIRECTED'
(1 row)
```

Returns the type of each outgoing edge from “Oliver”.

#### F.3.9.2.3. Match on Edge Label

When you know the edge label you want to match on, you can specify it by using a colon together with the edge label

```
SELECT * FROM cypher('graph_name', $$
MATCH (:Movie {title: 'Wall Street'})<-[ :ACTED_IN]-(actor)
RETURN actor.name
$$) as (actors_name agtype);
```

```
actors_name
-----
'Charlie Sheen'
'Martin Sheen'
'Michael Douglas'
(3 rows)
```

Returns all actors that `ACTED_IN` “Wall Street”.

#### F.3.9.2.4. Match on Edge Label with a Variable

If you want to use a variable to hold the edge, and specify the edge label you want, you can do so by specifying them both.

```
SELECT * FROM cypher('graph_name', $$
MATCH ({title: 'Wall Street'})<-[r:ACTED_IN]-(actor)
RETURN r.role
$$) as (role agtype);
```

```
role
-----
'Gordon Gekko'
'Carl Fox'
'Bud Fox'
(3 rows)
```

Returns `ACTED_IN` roles for “Wall Street”.

#### F.3.9.2.5. Multiple Edges

Edges can be strung together to match an infinite number of edges. As long as the base pattern `()-[]-` is followed, users can chain together edges and vertices to match specific patterns.

```
SELECT * FROM cypher('graph_name', $$
    MATCH (charlie {name: 'Charlie Sheen'})-[:ACTED_IN]->(movie)<-[:DIRECTED]-(
director)
    RETURN movie.title, director.name
$$) as (title agtype, name agtype);
```

| title         | name           |
|---------------|----------------|
| 'Wall Street' | 'Oliver Stone' |

(1 row)

Returns the movie “Charlie Sheen” acted in and its director.

#### F.3.9.3. Variable Length Edges

When the connection between two vertices is of variable length, the list of edges that form the connection can be returned using the following connection.

Rather than describing a long path using a sequence of many vertex and edge descriptions in a pattern, many edges (and the intermediate vertices) can be described by specifying a length in the edge description of a pattern.

`(u)-[*2]->(v)`

Which describes a right directed path of three vertices and two edges can be rewritten to:

`(u)-[]->()-[]->(v)`

A range length can also be given:

`(u)-[*3..5]->(v)`

Which is equivalent to:

`(u)-[]->()-[]->()-[]->(v)` and  
`(u)-[]->()-[]->()-[]->()-[]->(v)` and  
`(u)-[]->()-[]->()-[]->()-[]->()-[]->(v)`

The previous example provided gave the path both a lower and upper bound for the number of edges (and vertices) between `u` and `v`. Either one or both of these binding values can be excluded.

`(u)-[*3..]->(v)`

Returns all paths between `u` and `v` that have three or more edges included.

`(u)-[*..5]->(v)`

Returns all paths between `u` and `v` that have 5 or fewer edges included.

`(u)-[*]->(v)`

Returns all paths between `u` and `v`.

##### F.3.9.3.1. Example

```
SELECT * FROM cypher('graph_name', $$
    MATCH p = (actor {name: 'Willam Dafoe'})-[:ACTED_IN*2]-(co_actor)
```

```
RETURN relationships(p)
$$) as (r agtype);
```

r

```
-----
[{id: 0; label:"ACTED_IN"; properties: {role: "Green Goblin"}}::edge, {id: 1; label:
"ACTED_IN; properties: {role: "Spiderman", actor: "Toby Maguire"}}::edge]
[{id: 0; label:"ACTED_IN"; properties: {role: "Green Goblin"}}::edge, {id: 2; label:
"ACTED_IN; properties: {role: "Spiderman", actor: "Andrew Garfield"}}::edge]
(2 rows)
```

Returns the list of edges, including the one that “Willam Dafoe” acted in and the two “Spiderman” actors he worked with.

### F.3.10. WITH

Using `WITH`, you can manipulate the output before it is passed on to the following query parts. The manipulations can be of the shape and/or number of entries in the result set.

`WITH` can also, like `RETURN`, alias expressions that are introduced into the results using the aliases as the binding name.

`WITH` is also used to separate the reading of the graph from updating of the graph. Every part of a query must be either read-only or write-only. When going from a writing part to a reading part, an optional `WITH` clause can be used to do so.

#### F.3.10.1. Filter on Aggregate Function Results

Aggregated results have to pass through a `WITH` clause to be able to filter on.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (david {name: 'David'})-[]-(otherPerson)-[]->()
    WITH otherPerson, count(*) AS foaf
    WHERE foaf > 1
    RETURN otherPerson.name
$$) as (name agtype);
```

```
name
-----
"Anders"
(1 row)
```

The name of the person connected to “David” with the at least more than one outgoing relationship will be returned by the query.

#### F.3.10.2. Sort Results Before Using `collect`

You can sort results before passing them to `collect`, thus sorting the resulting list.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n)WITH n
    ORDER BY n.name DESC LIMIT 3
    RETURN collect(n.name)
$$) as (names agtype);
```

```
names
-----
["Emil", "David", "Ceasar"]
(1 row)
```

A list of the names of people in reverse order, limited to 3, is returned.

### F.3.10.3. Limit Branching of a Path Search

You can match paths, limit to a certain number, and then match again using those paths as a base, as well as any number of similar limited searches.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n {name: 'Anders'})-[]-(m) WITH m
    ORDER BY m.name DESC LIMIT 1
    MATCH (m)-[]-(o)
    RETURN o.name
$$) as (name agtype);
```

```
name
-----
"Anders"
"Bossmann"
(2 rows)
```

Starting at “Anders”, find all matching nodes, order by name descending and get the top result, then find all the nodes connected to that top result, and return their names.

## F.3.11. RETURN

In the `RETURN` part of your query, you define which parts of the pattern you want to output. Output can include `agtype` values, nodes, relationships, or properties.

### F.3.11.1. Return Nodes

To return a node, list it in the `RETURN` statement.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n {name: 'B'})
    RETURN n
$$) as (n agtype);
```

```
          n
-----
{id: 0; label: '' properties: {name: 'B'}}::vertex
(1 row)
```

The example will return the node.

### F.3.11.2. Return Edges

To return `n` edges, just include it in the `RETURN` list.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n)-[r:KNOWS]->()
    WHERE n.name = 'A'
    RETURN r
$$) as (r agtype);
```

```
          r
-----
{id: 2; startid: 0; endid: 1; label: 'KNOWS' properties: {}}::edge
(1 row)
```

The relationship is returned by the example.

### F.3.11.3. Return Property

To return a property, use the dot separator, as follows:

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n {name: 'A'})
    RETURN n.name
$$) as (name agtype);
```

```
name
-----
'A'
(1 row)
```

The value of the property `name` gets returned.

### F.3.11.4. Return All Elements

When you want to return all vertices, edges and paths found in a query, you can use the `*` symbol.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (a {name: 'A'})-[r]->(b)
    RETURN *
$$) as (a agtype, b agtype, r agtype);
```

```

                                     a
                                     |
                                     |
                                     b
                                     |
                                     |
                                     |
r
-----
+-----+
+-----+
{"id": 281474976710659, "label": "", "properties": {"age": 55, "name": "A",
"happy": "Yes!"}}::vertex | {"id": 1125899906842625, "label": "BLOCKS", "end_id":
281474976710660, "start_id": 281474976710659, "properties": {}}::edge | {"id":
281474976710660, "label": "", "properties": {"name": "B"}}::vertex
{"id": 281474976710659, "label": "", "properties": {"age": 55, "name": "A",
"happy": "Yes!"}}::vertex | {"id": 1407374883553281, "label": "KNOWS", "end_id":
281474976710660, "start_id": 281474976710659, "properties": {}}::edge | {"id":
281474976710660, "label": "", "properties": {"name": "B"}}::vertex
(2 rows)
```

This returns the two vertices, and the edge used in the query.

### F.3.11.5. Variable with Uncommon Characters

To introduce a placeholder that is made up of characters that are not contained in the English alphabet, you can use the ``` to enclose the variable, like this:

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (`This isn't a common variable`)
    WHERE `This isn't a common variable`.name = 'A'
    RETURN `This isn't a common variable`.happy
$$) as (happy agtype);
```

```
happy
```

```
-----  
"Yes!"  
(1 row)
```

The node with name “A” is returned.

### F.3.11.6. Aliasing a Field

If the name of the field should be different from the expression used, you can rename it by changing the name in the column list definition.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (n {name: 'A'})  
    RETURN n.name  
$$) as (objects_name agtype);  
  
objects_name  
-----  
'A'  
(1 row)
```

Returns the property of a node, but renames the field.

### F.3.11.7. Optional Properties

If a property might or might not be there, it will be treated as `null` if it is missing.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (n)  
    RETURN n.age  
$$) as (age agtype);  
  
age  
-----  
55  
NULL  
(2 rows)
```

This query returns the property if it exists, or `null` if the property does not exist.

### F.3.11.8. Other Expressions

Any expression can be used as a return item—literals, predicates, properties, functions, and everything else.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (a)  
    RETURN a.age > 30, 'I\'m a literal', id(a)  
$$) as (older_than_30 agtype, literal agtype, id agtype);  
  
older_than_30 | literal | id  
-----+-----+-----  
true | 'I'm a literal' | 1  
(1 row)
```

Returns a predicate, a literal and function call with a pattern expression parameter.

### F.3.11.9. Unique Results

`DISTINCT` retrieves only unique records depending on the fields that have been selected to output.

```
SELECT *
FROM cypher('graph_name', $$
MATCH (a {name: 'A'})-[]->(b)
RETURN DISTINCT b
$$) as (b agtype);
```

b

```
-----
{id: 1; label: '' properties: {name: 'B'}}::vertex
(1 row)
```

The node named “B” is returned by the query, but only once.

## F.3.12. ORDER BY

`ORDER BY` is a sub-clause following `WITH`. `ORDER BY` specifies that the output should be sorted and how it will be sorted.

Note that you cannot sort on nodes or relationships, sorting must be done on properties. `ORDER BY` relies on comparisons to sort the output. See [ordering and comparison of values](#).

In terms of scope of variables, `ORDER BY` follows special rules, depending on if the projecting `RETURN` or `WITH` clause is either aggregating or `DISTINCT`. If it is an aggregating or `DISTINCT` projection, only the variables available in the projection are available. If the projection does not alter the output cardinality (which aggregation and `DISTINCT` do), variables available from before the projecting clause are also available. When the projection clause shadows already existing variables, only the new variables are available.

Lastly, it is not allowed to use aggregating expressions in the `ORDER BY` sub-clause if they are not also listed in the projecting clause. This last rule is to make sure that `ORDER BY` does not change the results, only the order of them.

### F.3.12.1. Order Nodes by Property

`ORDER BY` is used to sort the output.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n)
    WITH n.name as name, n.age as age
    ORDER BY n.name
    RETURN name, age
$$) as (name agtype, age agtype);
```

```
name | age
-----+-----
"A"  | 34
"B"  | 34
"C"  | 32
(3 rows)
```

The nodes are returned, sorted by their name.

### F.3.12.2. Order Nodes by Multiple Properties

You can order by multiple properties by stating each variable in the `ORDER BY` clause. Cypher will sort the result by the first variable listed, and for equal values, go to the next property in the `ORDER BY` clause, and so on.

```
SELECT *
FROM cypher('graph_name', $$
```

```
MATCH (n)
WITH n.name as name, n.age as age
ORDER BY n.age, n.name
RETURN name, age
$$) as (name agtype, age agtype);
```

| name | age |
|------|-----|
| "C"  | 32  |
| "A"  | 34  |
| "B"  | 34  |

(3 rows)

This returns the nodes, sorted first by their age, and then by their name.

### F.3.12.3. Order Nodes in Descending Order

By adding `DESC[ENDING]` after the variable to sort on, the sort will be done in reverse order.

```
SELECT *
FROM cypher('graph_name', $$
  MATCH (n)
  WITH n.name AS name, n.age AS age
  ORDER BY n.name DESC
  RETURN name, age
$$) as (name agtype, age agtype);
```

| name | age |
|------|-----|
| "C"  | 32  |
| "B"  | 34  |
| "A"  | 34  |

(3 rows)

The example returns the nodes, sorted by their name in reverse order.

### F.3.12.4. Ordering null

When sorting the result set, `null` will always come at the end of the result set for ascending sorting, and first for descending sorting.

```
SELECT *
FROM cypher('graph_name', $$
  MATCH (n)
  WITH n.name AS name, n.age AS age, n.height AS height
  ORDER BY n.height
  RETURN name, age, height
$$) as (name agtype, age agtype, height agtype);
```

| name | age | height |
|------|-----|--------|
| "A"  | 34  | 170    |
| "C"  | 32  | 185    |
| "B"  | 34  | NULL   |

(3 rows)

The nodes are returned sorted by the length property, with a node without that property last.

## F.3.13. SKIP

`SKIP` defines from which record to start including the records in the output.

By using `SKIP`, the result set will get trimmed from the top. Please note that no guarantees are made on the order of the returned results unless specified by the `ORDER BY` clause. `SKIP` accepts any expression that evaluates to a positive integer.

### F.3.13.1. Skip First Three Rows

To return a subset of the result, starting from the top, use the following syntax:

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n)
    RETURN n.name
    ORDER BY n.name
    SKIP 3
$$) as (names agtype);
```

```
names
-----
"D"
"E"
(2 rows)
```

The name property of the matched node `n` is returned, with a limit of 3.

### F.3.13.2. Return Middle Two Rows

To return a subset of the result, starting in the middle, use this syntax:

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n)
    RETURN n.name
    ORDER BY n.name
    SKIP 1
    LIMIT 2
$$) as (names agtype);
```

```
names
-----
"B"
"C"
(2 rows)
```

Two vertices from the middle are returned.

### F.3.13.3. Using an Expression with SKIP to Return a Subset of Rows

Using an expression with `SKIP` to return a subset of the rows.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n)
    RETURN n.name
    ORDER BY n.name
    SKIP (3 * rand()) + 1
$$) as (a agtype);
```

```
names
-----
"C"
"D"
```

```
"E"  
(3 rows)
```

The first two vertices are skipped, and only the last three are returned in the result.

## F.3.14. LIMIT

`LIMIT` constrains the number of records in the output.

`LIMIT` accepts any expression that evaluates to a positive integer.

### F.3.14.1. Return a Subset of the Rows

To return a subset of the result, starting from the top, use this syntax:

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (n) RETURN n.name  
    ORDER BY n.name  
    LIMIT 3  
$$) as (names agtype);
```

```
names  
"A"  
"B"  
"C"  
3 rows
```

The node is returned, and no property `age` exists on it.

### F.3.14.2. Using an Expression with LIMIT to Return a Subset of Rows

`LIMIT` accepts any expression that evaluates to a positive integer as long as it is not referring to any external variables:

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (n)  
    RETURN n.name  
    ORDER BY n.name  
    LIMIT toInteger(3 * rand()) + 1  
$$) as (names agtype);
```

```
names  
-----  
"A"  
"B"  
(2 rows)
```

Returns one to three top items.

## F.3.15. CREATE

The `CREATE` clause is used to create graph vertices and edges.

### F.3.15.1. Terminal CREATE Clauses

A `CREATE` clause that is not followed by another clause is a terminal clause. When the Cypher query ends with a terminal clause, no results will be returned from the Cypher function call. However, the Cypher function call still requires a column list definition. When the Cypher query ends with a terminal node, define a single value in the column list definition: no data will be returned in this variable.

```
SELECT *
```

```
FROM cypher('graph_name', $$
    CREATE /* Create clause here, no following clause */
    $$) as (a agtype);

a
---
(0 rows)
```

### F.3.15.2. Create Single Vertex

Creating a single vertex is done by issuing the following query.

```
SELECT *
FROM cypher('graph_name', $$
    CREATE (n)
    $$) as (v agtype);

v
---
(0 rows)
```

Nothing is returned from this query.

### F.3.15.3. Create Multiple Vertices

Creating multiple vertices is done by separating them with a comma.

```
SELECT *
FROM cypher('graph_name', $$
    CREATE (n), (m)
    $$) as (v agtype);

a
-----
(0 rows)
```

### F.3.15.4. Create a Vertex with a Label

To add a label when creating a vertex, use the syntax below.

```
SELECT *
FROM cypher('graph_name', $$
    CREATE (:Person)
    $$) as (v agtype);

v
-----
(0 rows)
```

Nothing is returned from this query.

### F.3.15.5. Create Vertex and Add Labels and Properties

You can create a vertex with labels and properties at the same time.

```
SELECT *
FROM cypher('graph_name', $$
    CREATE (:Person {name: 'Andres', title: 'Developer'})
    $$) as (n agtype);

n
```

```
-----  
(0 rows)
```

Nothing is returned from this query.

### F.3.15.6. Return Created Node

You can create and return a node within the same query as follows:

```
SELECT *  
FROM cypher('graph_name', $$  
    CREATE (a {name: 'Andres'})  
    RETURN a  
$$) as (a agtype);
```

a

```
-----  
{ "id": 281474976710660, "label": "", "properties": { "name": "Andres" } }::vertex  
(1 row)
```

The newly-created node is returned.

### F.3.15.7. Create an Edge Between Two Nodes

To create an edge between two vertices, we first `MATCH` the two vertices. Once the nodes are matched, we create an edge between them.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (a:Person), (b:Person)  
    WHERE a.name = 'Node A' AND b.name = 'Node B'  
    CREATE (a)-[e:RELTYPE]->(b)  
    RETURN e  
$$) as (e agtype);
```

e

```
-----  
{id: 3; startid: 0, endid: 1; label: 'RELTYPE'; properties: {}}::edge  
(1 row)
```

The created edge is returned by the query.

### F.3.15.8. Create an Edge and Set Properties

Setting properties on edges is done in a similar manner to setting properties when creating vertices. Note that the values can be any expression.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (a:Person), (b:Person)  
    WHERE a.name = 'Node A' AND b.name = 'Node B'  
    CREATE (a)-[e:RELTYPE {name:a.name + '<->' + b.name}]->(b)  
    RETURN e  
$$) as (e agtype);
```

e

```
-----  
{id: 3; startid: 0, endid: 1; label: 'RELTYPE'; properties: {name: 'Node A<->Node  
B'}}::edge  
(1 row)
```

The newly created edge is returned by the example query.

### F.3.15.9. Create a Full Path

When you use `CREATE` and a pattern, all parts of the patterns that are not already in scope at this time will be created.

```
SELECT *
FROM cypher('graph_name', $$
    CREATE p = (andres {name:'Andres'})-[:WORKS_AT]->(neo)<-[:WORKS_AT]-(michael
    {name:'Michael'})
    RETURN p
$$) as (p agtype);
```

p

---

```
[{"id": 281474976710661, "label": "", "properties": {"name": "Andres"}}::vertex,
{"id": 1407374883553282, "label": "WORKS_AT", "end_id": 281474976710662, "start_id":
281474976710661, "properties": {}}::edge, {"id": 281474976710662, "label": "",
"properties": {}}::vertex, {"id": 1407374883553281, "label": "WORKS_AT", "end_id":
281474976710662, "start_id": 281474976710663, "properties": {}}::edge, {"id":
281474976710663, "label": "", "properties": {"name": "Michael"}}::vertex]::path
(1 row)
```

This query creates three nodes and two relationships simultaneously, assigns the pattern to a path variable, and returns the said pattern.

### F.3.16. DELETE

The `DELETE` clause is used to delete graph elements — nodes, relationships, or paths.

A `DELETE` clause that is not followed by another clause is called a terminal clause. When the Cypher query ends with a terminal clause, no results will be returned from the Cypher function call. However, the Cypher function call still requires a column list definition. When the Cypher query ends with a terminal node, define a single value in the column list definition: no data will be returned in this variable.

For removing properties, see [Section F.3.17.4](#).

You cannot delete a node without also deleting edges that start or end on said vertex. Either explicitly delete the vertices, or use `DETACH DELETE`.

#### F.3.16.1. Delete Isolated Vertices

To delete a vertex, use the `DELETE` clause.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (v:Useless)
    DELETE v
$$) as (v agtype);
```

v

---

(0 rows)

This will delete the vertices (with label `Useless`) that have no edges. Nothing is returned from this query.

#### F.3.16.2. Delete All Vertices and Edges Associated with Them

Running a `MATCH` clause will collect all nodes — use the `DETACH` option to delete vertex edges first, and then delete the vertex itself.

```
SELECT *
```

```
FROM cypher('graph_name', $$  
    MATCH (v:Useless)  
    DETACH DELETE v  
$$) as (v agtype);
```

v

-----

(0 rows)

Nothing is returned from this query.

### F.3.16.3. Delete Edges Only

To delete an edge, use the `MATCH` clause to find your edges, then add the variable to the `DELETE` clause.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (n {name: 'Andres'})-[r:KNOWS]->()  
    DELETE r  
$$) as (v agtype);
```

v

-----

(0 rows)

Nothing is returned from this query.

### F.3.16.4. Return a Deleted Vertex

You can return vertices that have been deleted with a `RETURN` clause.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (n {name: 'A'})  
    DELETE n  
    RETURN n  
$$) as (a agtype);
```

a

-----  
{ "id": 281474976710659, "label": "", "properties": { "name": "A" } }::vertex  
(1 rows)

## F.3.17. SET

The `SET` clause is used to update labels and properties on vertices and edges.

### F.3.17.1. Terminal SET Clauses

A `SET` clause that is not followed by another clause is a terminal clause. When the Cypher query ends with a terminal clause, no results will be returned from the Cypher function call. However, the Cypher function call still requires a column list definition. When the Cypher query ends with a terminal node, define a single value in the column list definition: no data will be returned in this variable.

### F.3.17.2. Set a Property

To set a property on a node or relationship, use `SET`.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (v {name: 'Andres'})  
    SET v.surname = 'Taylor'
```

```
$$) as (v agtype);
```

```
v
```

```
-----
```

```
(0 rows)
```

The newly changed node is returned by the query.

### F.3.17.3. Return Created Vertex

Creating a single vertex is done with the following query:

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (v {name: 'Andres'})
    SET v.surname = 'Taylor'
    RETURN v
$$) as (v agtype);
```

```
v
```

```
-----
{id: 3; label: 'Person'; properties: {surname:"Taylor", name:"Andres", age:36,
hungry:true}}::vertex
```

```
(1 row)
```

The newly changed vertex is returned by the query.

### F.3.17.4. Remove a Property

Normally a property can be removed by using `REMOVE`, but users can also remove properties using the `SET` command. One example is if the property comes from a parameter.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (v {name: 'Andres'})
    SET v.name = NULL
    RETURN v
$$) as (v agtype);
```

```
v
```

```
-----
{id: 3; label: 'Person'; properties: {surname:"Taylor", age:36, hungry:true}}::vertex
(1 row)
```

The node is returned by the query, and the name property is now missing.

### F.3.17.5. Set Multiple Properties Using One SET Clause

If you want to set multiple properties in one query, you can separate them with a comma.

```
SELECT *
FROM cypher('graph_name', $$
MATCH (v {name: 'Andres'})
SET v.position = 'Developer', v.surname = 'Taylor'
RETURN v
$$) as (v agtype);
```

```
v
```

```
-----
{"id": 281474976710661, "label": "", "properties": {"name": "Andres", "surname":
"Taylor", "position": "Developer"}}: :vertex
(1 row)
```

## F.3.18. REMOVE

The `REMOVE` clause is used to remove properties from vertex and edges.

A `REMOVE` clause that is not followed by another clause is called a terminal clause. When the Cypher query ends with a terminal clause, no results will be returned from the Cypher function call. However, the Cypher function call still requires a column list definition. When the Cypher query ends with a terminal node, define a single value in the column list definition: no data will be returned in this variable.

Cypher does not allow storing `null` in properties. Instead, if no value exists, the property is just not there. So, removing a property value on a node or a relationship is also done with `REMOVE`.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (andres {name: 'Andres'})
    REMOVE andres.age
    RETURN andres
$$) as (andres agtype);

-----
andres

{id: 3; label: 'Person'; properties: {name:"Andres"}}::vertex
(1 row)
```

The node is returned, and no property `age` exists on it.

## F.3.19. MERGE

The `MERGE` clause ensures that a pattern exists in the graph. Either the pattern already exists, or it needs to be created.

`MERGE` either matches existing nodes, or creates new data. It is a combination of `MATCH` and `CREATE`.

For example, you can specify that the graph must contain a node for a user with a certain name. If there is not a node with the correct name, a new node will be created and its name property set. When using `MERGE` on full patterns, the behavior is that either the whole pattern matches, or the whole pattern is created. `MERGE` will not partially use existing patterns. If partial matches are needed, this can be accomplished by splitting a pattern up into multiple `MERGE` clauses.

As with `MATCH`, `MERGE` can match multiple occurrences of a pattern. If there are multiple matches, they will all be passed on to later stages of the query.

```
SELECT * from cypher('graph_name', $$
CREATE (A:Person {name: 'Charlie Sheen', bornIn: 'New York'}),
      (B:Person {name: 'Michael Douglas', bornIn: 'New Jersey'}),
      (C:Person {name: 'Rob Reiner', bornIn: 'New York'}),
      (D:Person {name: 'Oliver Stone', bornIn: 'New York'}),
      (E:Person {name: 'Martin Sheen', bornIn: 'Ohio'})
$$) as (result agtype);
```

### F.3.19.1. Merge Nodes

#### F.3.19.1.1. Merge a Node with a Label

By just specifying a pattern with a single vertex and no labels, all vertices in the graph will be returned.

```
SELECT * FROM cypher('graph_name', $$
MERGE (v:Critic)
RETURN v
$$) as (v agtype);
```

v

```
-----  
{id: 0; label: 'Critic': properties:{}::vertex  
(1 row)
```

If there exists a vertex with the label “Critic”, that vertex will be returned. Otherwise, the vertex will be created and returned.

#### F.3.19.1.2. Merge Single Vertex with Properties

Merging a vertex node with properties where not all properties match any existing vertex.

```
SELECT * FROM cypher('graph_name', $$  
MERGE (charlie {name: 'Charlie Sheen', age: 10})  
RETURN charlie  
$$) as (v agtype);
```

v

```
-----  
{id: 0; label: 'Actor': properties:{name: 'Charlie Sheen', age: 10}}::vertex  
(1 row)
```

If there exists a vertex with the label “Critic”, that vertex will be returned. Otherwise, the vertex will be created and returned.

If there exists a vertex with all properties, that vertex will be returned. Otherwise, a new vertex with the name “Charlie Sheen” will be created and returned.

#### F.3.19.1.3. Merge a Single Vertex Specifying Both Label and Property

Merging a vertex where both label and property constraints match an existing vertex.

```
SELECT * FROM cypher('graph_name', $$  
MERGE (michael:Person {name: 'Michael Douglas'})  
RETURN michael.name, michael.bornIn  
$$) as (Name agtype, BornIn agtype);
```

| name              | bornin       |
|-------------------|--------------|
| "Michael Douglas" | "New Jersey" |

```
-----+-----  
(1 row)
```

“Michael Douglas” will match the existing vertex, and the vertex `name` and `bornIn` properties will be returned.

## F.3.20. Predicate Functions

Predicates are boolean functions that return true or false for a given set of input. They are most commonly used to filter out subgraphs in the `WHERE` part of a query.

`exists(property agtype)` returns agtype boolean

`exists()` returns true if the specified property exists in the node, relationship or map. This is different from the `EXISTS` clause.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (n)  
    WHERE exists(n.surname)  
    RETURN n.first_name, n.last_name  
$$) as (first_name agtype, last_name agtype);  
  
first_name | last_name
```

```
-----+-----  
  'John'   |   'Smith'  
  'Patty'  | 'Patterson'  
(2 rows)
```

`exists(path agtype)` returns `agtype` boolean

`exists()` returns true if for the given path, there already exists the given path.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (n)  
    WHERE exists((n)-[]-({name: 'Willem Defoe'}))  
    RETURN n.full_name  
$$) as (full_name agtype);  
  
full_name  
-----  
'Toby Maguire'  
'Tom Holland'  
(2 rows)
```

### F.3.21. Scalar Functions

`id(expression agtype)` returns `agtype` integer

`id()` returns the ID of a vertex or edge.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (a)  
    RETURN id(a)  
$$) as (id agtype);  
  
id  
----  
0  
1  
2  
3  
(4 rows)
```

`start_id(expression agtype)` returns `agtype` integer

`start_id()` returns the ID of the vertex that is the starting vertex for the edge.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH ()-[e]->()  
    RETURN start_id(e)  
$$) as (start_id agtype);  
  
start_id  
-----  
0  
1  
2  
3  
(4 rows)
```

`end_id(expression agtype)` returns `agtype` integer

`end_id()` returns the ID of the vertex that is the ending vertex for the edge.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH ()-[e]->()
    RETURN end_id(e)
$$) as (end_id agtype);

end_id
-----
4
5
6
7
(4 rows)
```

`type(edge agtype)` returns agtype string

`type()` returns the string representation of the edge type.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH ()-[e]->()
    RETURN type(e)
$$) as (type agtype);

type
-----
'KNOWS'
'KNOWS'
(2 rows)
```

`properties(expression agtype)` returns agtype map

`properties()` returns an agtype map containing all the properties of a vertex or edge. If the argument is already a map, it is returned unchanged. `properties(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    CREATE (p:Person {name: 'Stefan', city: 'Berlin'})
    RETURN properties(p)
$$) as (type agtype);

type
-----
{"city": "Berlin", "name": "Stefan"}
(1 row)
```

`head(list agtype)` returns agtype

`head()` returns the first element in an agtype list. `head(null)` returns null. If the first element in the list is null, `head(list)` will return null.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (a)
    WHERE a.name = 'Eskil'
    RETURN a.array, head(a.array)
$$) as (lst agtype, lst_head agtype);

lst | lst_head
-----+-----
["one", "two", "three"] | "one"
```

(1 row)

`last(list agtype)` returns `agtype`

`last()` returns the last element in an `agtype` list. `last(null)` returns `null`. If the last element in the list is `null`, `last(list)` will return `null`.

```
SELECT *
FROM cypher('graph_name', $$
MATCH (a)
WHERE a.name = 'Eskil'
RETURN a.array, last(a.array)
$$) as (lst agtype, lst_tail agtype);
```

```
          lst          | lst_tail
-----+-----
["one","two","three"] | "three"
(1 row)
```

`length(path agtype)` returns `agtype integer`

`length()` returns the length of a path. `length(null)` returns `null`.

```
SELECT *
FROM cypher('graph_name', $$
  MATCH p = (a)-[]->(b)-[]->(c)
  WHERE a.name = 'Alice'
  RETURN length(p)
$$) as (length_of_path agtype);
```

```
length_of_path
-----
2
2
2
(3 rows)
```

`size(list variadic "any")` returns `agtype integer`

`size()` returns the length of a list. `size(null)` returns `null`.

```
SELECT *
FROM cypher('graph_name', $$
  RETURN size(['Alice', 'Bob'])
$$) as (size_of_list agtype);
```

```
size_of_list
-----
2
(1 row)
```

`startNode(edge agtype)` returns `agtype`

`startNode()` returns the start node of an edge. `startNode(null)` returns `null`.

```
SELECT *
FROM cypher('graph_name', $$
  MATCH (x:Developer)-[r]-()
  RETURN startNode(r)
$$) as (v agtype);
```

```
          v
-----
```

```
Node[0]{name:"Alice",age:38,eyes:"brown"}
Node[0]{name:"Alice",age:38,eyes:"brown"}
(2 rows)
```

`endNode(edge agtype)` returns `agtype`

`endNode()` returns the end node of an edge. `endNode(null)` returns `null`.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (x:Developer)-[r]-()
    RETURN endNode(r)
$$) as (v agtype);
```

v

```
-----
Node[2]{name:"Charlie",age:53,eyes:"green"}
Node[1]{name:"Bob",age:25,eyes:"blue"}
(2 rows)
```

`timestamp()` returns `agtype integer`

`timestamp()` returns the difference, measured in milliseconds, between the current time and midnight, January 1, 1970 UTC. `timestamp` will return the same value during one entire query, even for long-running queries.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN timestamp()
$$) as (t agtype);
```

t

```
-----
1613496720760
(1 row)
```

`toBoolean(expression variadic "any")` returns `agtype boolean`

`toBoolean()` converts a string value to a boolean value. `toBoolean(null)` returns `null`. If `expression` is a boolean value, it will be returned unchanged. If the parsing fails, `null` will be returned.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN toBoolean('TRUE'), toBoolean('not a boolean')
$$) as (a_bool agtype, not_a_bool agtype);
```

```
  a_bool | not_a_bool
-----+-----
   true  | NULL
(1 row)
```

`toFloat(expression variadic "any")` returns `agtype float`

`toFloat()` converts an integer or string value to a floating point number. `toFloat(null)` returns `null`. If `expression` is a floating point number, it will be returned unchanged. If the parsing fails, `null` will be returned.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN toFloat('11.5'), toFloat('not a number')
$$) as (a_float agtype, not_a_float agtype);
```

```
  a_float | not_a_float
```

```
-----+-----
11.5    | NULL
(1 row)
```

`toInteger(expression variadic "any")` returns agtype integer

`toInteger()` converts a floating point or string value to an integer value. `toInteger(null)` returns null. If expression is an integer value, it will be returned unchanged. If the parsing fails, null will be returned.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN toInteger('42'), toInteger('not a number')
$$) as (an_integer agtype, not_an_integer agtype);
```

```
an_integer | not_an_integer
-----+-----
42         | NULL
(1 row)
```

`coalesce(expression agtype [, expression agtype]*)` returns agtype

`coalesce()` returns the first non-null value in the given list of expressions. null will be returned if all the arguments are null.

```
SELECT *
FROM cypher('graph_name', $$
MATCH (a)
WHERE a.name = 'Alice'
RETURN coalesce(a.hairColor, a.eyes), a.hair_color, a.eyes
$$) as (color agtype, hair_color agtype, eyes agtype);
```

```
color | hair_color | eyes
-----+-----+-----
"brown"| NULL      | "Brown"
(1 row)
```

## F.3.22. List Functions

```
SELECT * from cypher('graph_name', $$
CREATE (A:Person {name: 'Alice', age: 38, eyes: 'brown'}),
      (B:Person {name: 'Bob', age: 25, eyes: 'blue'}),
      (C:Person {name: 'Charlie', age: 53, eyes: 'green'}),
      (D:Person {name: 'Daniel', age: 54, eyes: 'brown'}),
      (E:Person {name: 'Eskil', age: 41, eyes: 'blue', array: ['one', 'two', 'three']}),
      (A)-[:KNOWS]->(B),
      (A)-[:KNOWS]->(C),
      (B)-[:KNOWS]->(D),
      (C)-[:KNOWS]->(D),
      (B)-[:KNOWS]->(E)
$$) as (result agtype);
```

`keys(expression agtype)` returns agtype list

`keys()` returns a list containing the string representations for all the property names of a vertex, edge, or map. `keys(null)` returns null.

```
SELECT * from cypher('graph_name', $$
MATCH (a)
WHERE a.name = 'Alice'
RETURN keys(a)
$$) as (result agtype);
```

```
result
-----
["age", "eyes", "name"]
(1 row)
```

A list containing the names of all the properties on the vertex bound to `a` is returned.

`range(start variadic "any", end variadic "any" [, step variadic "any"])` returns agtype list

`range()` returns a list comprising all integer values within a range bounded by a start value *start* and end value *end*, where the difference *step* between any two consecutive values is constant; i.e. an arithmetic progression. The range is inclusive, and the arithmetic progression will therefore always contain *start* and — depending on the values of *start*, *step*, and *end* — *end*.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN range(0, 10), range(2, 18, 3)
$$) as (no_step agtype, step agtype);
```

| no_step                            |  | step                  |
|------------------------------------|--|-----------------------|
| [0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10] |  | [2, 5, 8, 11, 14, 17] |

```
(1 row)
```

Two lists of numbers in the given ranges are returned.

`labels(vertex agtype)` returns agtype list

`labels()` returns a list containing the string representations for all the labels of a node. `labels(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (a)
    WHERE a.name = 'Alice'
    RETURN labels(a)
$$) as (edges agtype);
```

```
edges
-----
["Person"]
(1 row)
```

A list containing all the labels of the node bound to `a` is returned.

`nodes(path agtype)` returns agtype list

`nodes()` returns a list containing all the vertices in a path. `nodes(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH p = (a)-[]->(b)-[]->(c)
    WHERE a.name = 'Alice' AND c.name = 'Eskil'
    RETURN nodes(p)
$$) as (vertices agtype);
```

```
vertices
-----
```

```

"brown", "name": "Alice"}}::vertex, {"id": 844424930131970, "label": "Person",  
"properties": {"age": 25, "eyes": "blue", "name": "Bob"}}::vertex, {"id":  
844424930131973, "label": "Person", "properties": {"age": 41, "eyes": "blue",  
"name": "Eskil", "array": ["one", "two", "three"]}}::vertex]  
(1 row)
```

A list containing all the vertices in the path `p` is returned.

`relationships(path agtype)` returns `agtype` list

`relationships()` returns a list containing all the relationships in a path. `relationships(null)` returns `null`.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH p = (a)-[]->(b)-[]->(c)  
    WHERE a.name = 'Alice' AND c.name = 'Eskil'  
    RETURN relationships(p)  
$$) as (edges agtype);
```

edges

---

```
[{"id": 1125899906842625, "label": "KNOWS", "end_id": 844424930131970, "start_id":

{}}::edge]  
(1 row)
```

A list containing all the edges in the path `p` is returned.

`toBooleanList(list variadic "any")` returns `agtype` list

`toBooleanList()` converts a list of values and returns a list of boolean values. If any values are not convertible to boolean they will be `null` in the list returned. Any `null` element in list is preserved. Any boolean value in list is preserved. If the list is `null`, `null` will be returned.

```
SELECT * FROM cypher('expr', $$  
    RETURN toBooleanList(['true', 'false', 'true'])  
$$) AS (toBooleanList agtype);
```

toBooleanList

---

```
[true, false, true]  
(1 row)
```

## F.3.23. Numeric Functions

`rand()` returns `agtype` float

`rand()` returns a random floating point number in the range from 0 (inclusive) to 1 (exclusive); i.e. [0,1). The numbers returned follow an approximate uniform distribution.

```
SELECT *  
FROM cypher('graph_name', $$  
    RETURN rand()  
$$) as (random_number agtype);
```

random\_number

---

```
0.3586784748902053
```

(1 row)

`abs(list variadic "any")` returns agtype

`abs()` returns the absolute value of the given number. `abs(null)` returns null. If expression is negative, `-(expression)` (i.e. the negation of expression) is returned.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (a), (e) WHERE a.name = 'Alice' AND e.name = 'Eskil'
    RETURN a.age, e.age, abs(a.age - e.age)
$$) as (alice_age agtype, eskil_age agtype, difference agtype);
```

| alice_age | eskil_age | difference |
|-----------|-----------|------------|
| 38        | 41        | 3          |

(1 row)

The absolute value of the age difference is returned.

`ceil(expression variadic "any")` returns agtype float

`ceil()` returns the smallest floating point number that is greater than or equal to the given number and equal to a mathematical integer. `ceil(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN ceil(0.1)
$$) as (ceil_value agtype);
```

| ceil_value |
|------------|
| 1.0        |

(1 row)

The ceiling of 0.1 is returned.

`floor(expression variadic "any")` returns agtype float

`floor()` returns the greatest floating point number that is less than or equal to the given number and equal to a mathematical integer. `floor(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN floor(0.1)
$$) as (flr agtype);
```

| flr |
|-----|
| 0.0 |

(1 row)

The floor of 0.1 is returned.

`round(expression variadic "any")` returns agtype float

`round()` returns the value of the given number rounded to the nearest integer. `round(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN round(3.141592)
$$) as (rounded_value agtype);
```

```
rounded_value
-----
3.0
(1 row)
```

`sign(expression variadic "any")` returns agtype integer

`sign()` returns the signum of the given number: 0 if the number is 0, -1 for any negative number, and 1 for any positive number. `sign(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN sign(-17), sign(0.1), sign(0)
$$) as (negative_sign agtype, positive_sign agtype, zero_sign agtype);
```

```
negative_sign | positive_sign | zero_sign
-----+-----+-----
-1            | 1             | 0
(1 row)
```

The signs of -17 and 0.1 are returned.

### F.3.24. Logarithmic Functions

`e()` returns agtype float

`e()` returns the base of the natural logarithm, e.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN e()
$$) as (e agtype);
```

```
          e
-----
2.718281828459045
(1 row)
```

`sqrt(expression variadic "any")` returns agtype float

`sqrt()` returns the square root of a number.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN sqrt(144)
$$) as (results agtype);
```

```
results
-----
12.0
(1 row)
```

`exp(expression variadic "any")` returns agtype float

`exp()` returns  $e^n$ , where e is the base of the natural logarithm, and n is the value of the argument expression. `exp(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN exp(2)
$$) as (e agtype);
```

```
      e
-----
 7.38905609893065
(1 row)
```

`e` to the power of 2 is returned.

`log(expression variadic "any")` returns agtype float

`log()` returns the natural logarithm of a number. `log(null)` returns null. `log(0)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN log(27)
$$) as (natural_logarithm agtype);
```

```
      natural_logarithm
-----
 3.295836866004329
(1 row)
```

The natural logarithm of 27 is returned.

`log10(expression variadic "any")` returns agtype float

`log10()` returns the common logarithm (base 10) of a number. `log10(null)` returns null. `log10(0)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN log10(27)
$$) as (common_logarithm agtype);
```

```
      common_logarithm
-----
 1.4313637641589874
(1 row)
```

The common logarithm of 27 is returned.

## F.3.25. Trigonometric Functions

`degrees(expression variadic "any")` returns agtype float

`degrees()` converts radians to degrees. `degrees(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN degrees(3.14159)
$$) as (deg agtype);
```

```
      deg
-----
 179.9998479605043
(1 row)
```

The number of degrees close to pi is returned.

`radians(expression variadic "any")` returns agtype float

`radians()` converts degrees to radians. `radians(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
```

```
RETURN radians(180)
$$) as (rad agtype);
```

```
rad
-----
3.141592653589793
(1 row)
```

The number of degrees close to pi is returned.

`pi()` returns agtype float

`pi()` returns the mathematical constant pi.

```
SELECT *
FROM cypher('graph_name', $$
RETURN pi()
$$) as (p agtype);
```

```
p
-----
3.141592653589793
(1 row)
```

The constant pi is returned.

`sin(expression variadic "any")` returns agtype float

`sin()` returns the sine of a number. `sin(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
RETURN sin(0.5)
$$) as (s agtype);
```

```
s
-----
0.479425538604203
(1 row)
```

The sine of 0.5 is returned.

`cos(expression variadic "any")` returns agtype float

`cos()` returns the sine of a number. `cos(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
RETURN cos(0.5)
$$) as (c agtype);
```

```
c
-----
0.8775825618903728
(1 row)
```

The cosine of 0.5 is returned.

`tan(expression variadic "any")` returns agtype float

`tan()` returns the tangent of a number. `tan(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
```

```
RETURN tan(0.5)
$$) as (t agtype);
```

```

      t
-----
0.5463024898437905
(1 row)
```

The tangent of 0.5 is returned.

`cot(expression variadic "any")` returns agtype float

`cot()` returns the cotangent of a number. `cot(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN cot(0.5)
$$) as (t agtype);
```

```

      t
-----
1.830487721712452
(1 row)
```

The cotangent of 0.5 is returned.

`asin(expression variadic "any")` returns agtype float

`asin()` returns the arcsine of a number. `asin(null)` returns null. If (expression < -1) or (expression > 1), then `asin(expression)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN asin(0.5)
$$) as (arc_s agtype);
```

```

      arc_s
-----
0.5235987755982989
(1 row)
```

The arcsine of 0.5 is returned.

`acos(expression variadic "any")` returns agtype float

`acos()` returns the arcsine of a number. `acos(null)` returns null. If (expression < -1) or (expression > 1), then `acos(expression)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN acos(0.5)
$$) as (arc_c agtype);
```

```

      arc_c
-----
1.0471975511965979
(1 row)
```

The arccosine of 0.5 is returned.

`atan(expression variadic "any")` returns agtype float

`atan()` returns the arctangent of a number. `atan(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN atan(0.5)
$$) as (arc_t agtype);
```

```
      arc_t
-----
0.4636476090008061
(1 row)
```

The arctangent of 0.5 is returned.

`atan2(expression1 variadic "any", expression2 variadic "any")` returns agtype float  
`atan2()` returns the arctangent of a set of coordinates in radians. `atan2(null, null)`, `atan2(null, expression2)` and `atan(expression1, null)` all return null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN atan2(0.5, 0.6)
$$) as (arc_t2 agtype);
```

```
      arc_t2
-----
0.6947382761967033
(1 row)
```

The arctangent of 0.5 and 0.6 is returned.

## F.3.26. String Functions

`replace(original, search variadic "any", replace variadic "any")` returns agtype string  
`replace()` returns a string in which all occurrences of a specified string in the original string have been replaced by another (specified) string. If any argument is null, null will be returned. If search is not found in *original*, *original* will be returned.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN replace('hello', 'l', 'w')
$$) as (str_array agtype);
```

```
      str_array
-----
"hewwwo"
(1 row)
```

`split(original variadic "any", split_delimiter variadic "any")` returns list of agtype strings

`split()` returns a list of strings resulting from the splitting of the original string around matches of the given delimiter. `split(null, splitDelimiter)` and `split(original, null)` both return null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN split('one,two', ',')
$$) as (split_list agtype);
```

```
      split_list
-----
["one", "two"]
```

(1 row)

`left(original variadic "any", length variadic "any")` returns agtype string

`left()` returns a string containing the specified number of leftmost characters of the original string. `left(null, length)` and `left(null, null)` both return null. `left(original, null)` will raise an error. If *length* is not a positive integer, an error is raised. If *length* exceeds the size of *original*, *original* is returned.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN left('Hello', 3)
$$) as (new_str agtype);
```

```
new_str
-----
"Hel"
(1 row)
```

`right(original variadic "any", length variadic "any")` returns agtype string

`right()` returns a string containing the specified number of rightmost characters of the original string. `right(null, length)` and `right(null, null)` both return null. `right(original, null)` will raise an error. If *length* is not a positive integer, an error is raised. If *length* exceeds the size of *original*, *original* is returned.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN right('hello', 3)
$$) as (new_str agtype);
```

```
new_str
-----
"llo"
(1 row)
```

`substring(original variadic "any", start variadic "any" [, length variadic "any"])` returns agtype string

`substring()` returns a substring of the original string, beginning with a 0-based index *start* and *length*. *start* uses a zero-based index. If *length* is omitted, the function returns the substring starting at the position given by *start* and extending to the end of *original*. If *original* is null, null is returned. If either *start* or *length* is null or a negative integer, an error is raised. If *start* is 0, the substring will start at the beginning of *original*. If *length* is 0, the empty string will be returned.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN substring('hello', 1, 3), substring('hello', 2)
$$) as (sub_str1 agtype, sub_str2 agtype);
```

```
sub_str1 | sub_str2
-----+-----
"ell"    | "llo"
(1 row)
```

`rTrim(original variadic "any")` returns agtype string

`rTrim()` returns the original string with trailing whitespace removed. `rTrim(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN rTrim(' hello ')
```

```
$$) as (right_trimmed_str agtype);
```

```
right_trimmed_str
-----
" hello"
(1 row)
```

`lTrim(original variadic "any")` returns agtype string

`lTrim()` returns the original string with leading whitespace removed. `lTrim(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN lTrim(' hello ')
$$) as (left_trimmed_str agtype);
```

```
left_trimmed_str
-----
"hello "
(1 row)
```

`trim(original variadic "any")` returns agtype string

`trim()` returns the original string with leading and trailing whitespace removed. `trim(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN trim(' hello ')
$$) as (trimmed_str agtype);
```

```
trimmed_str
-----
"hello"
(1 row)
```

`toLower(original variadic "any")` returns agtype string

`toLower()` returns the original string in lowercase. `toLower(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN toLower('HELLO')
$$) as (lower_str agtype);
```

```
lower_str
-----
"hello"
(1 row)
```

`toUpper(original variadic "any")` returns agtype string

`toUpper()` returns the original string in uppercase. `toUpper(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN toUpper('hello')
$$) as (upper_str agtype);
```

```
upper_str
-----
"HELLO"
(1 row)
```

`reverse(original variadic "any")` returns agtype string

`reverse()` returns a string in which the order of all characters in the original string have been reversed. `reverse(null)` returns null.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN reverse('hello')
$$) as (reverse_str agtype);
```

```
reverse_str
-----
"olleh"
(1 row)
```

`toString(expression agtype)` returns string

`toString()` converts an integer, float or boolean value to a string. `toString(null)` returns null. If *expression* is a string, it will be returned unchanged.

```
SELECT *
FROM cypher('graph_name', $$
    RETURN toString(11.5), toString('a string'), toString(true)
$$) as (float_to_str agtype, str_to_str agtype, bool_to_string agtype);
```

```
float_to_str | str_to_str | bool_to_string
-----+-----+-----
"11.5"       | "a string" | "true"
(1 row)
```

## F.3.27. Aggregation Functions

Functions that activate [auto aggregation](#).

```
LOAD 'age';
SET search_path TO ag_catalog;
```

```
SELECT create_graph('graph_name');
```

```
SELECT * FROM cypher('graph_name', $$
    CREATE (a:Person {name: 'A', age: 13}),
    (b:Person {name: 'B', age: 33, eyes: 'blue'}),
    (c:Person {name: 'C', age: 44, eyes: 'blue'}),
    (d1:Person {name: 'D', eyes: 'brown'}),
    (d2:Person {name: 'D'}),
    (a)-[:KNOWS]->(b),
    (a)-[:KNOWS]->(c),
    (a)-[:KNOWS]->(d1),
    (b)-[:KNOWS]->(d2),
    (c)-[:KNOWS]->(d2)
$$) as (a agtype);
```

`min(expression variadic "any")` returns agtype

`min()` returns the minimum value in a set of values. Any null values are excluded from the calculation. In a mixed set, any string value is always considered to be lower than any numeric value, and any list is always considered to be lower than any string. Lists are compared in dictionary order, i.e. list elements are compared pairwise in ascending order from the start of the list to the end. `min(null)` returns null.

```
SELECT *
```

```
FROM cypher('graph_name', $$  
    MATCH (v:Person)  
    RETURN min(v.age)  
$$) as (min_age agtype);
```

```
min_age  
-----  
13  
(1 row)
```

The lowest of all the values in the property `age` is returned.

To clarify the following example, assume the next three commands are run first:

```
SELECT * FROM cypher('graph_name', $$  
    CREATE (:min_test {val:'d'})  
$$) as (result agtype);  
  
SELECT * FROM cypher('graph_name', $$  
    CREATE (:min_test {val:['a', 'b', 23]})  
$$) as (result agtype);  
  
SELECT * FROM cypher('graph_name', $$  
    CREATE (:min_test {val:[1, 'b', 23]})  
$$) as (result agtype);
```

The example below shows using `min()` with lists:

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (v:min_test)  
    RETURN min(v.val)  
$$) as (min_val agtype);
```

```
min_val  
-----  
["a", "b", 23]  
(1 row)
```

The lowest of all the values in the set is returned (in this case, the list `["a", "b", 23]`), as the two lists are considered to be lower values than the string `"d"`, and the string `"a"` is considered to be a lower value than the numerical value `1`.

`max(expression variadic "any")` returns agtype float

`max()` returns the maximum value in a set of values. Any `null` values are excluded from the calculation. In a mixed set, any numeric value is always considered to be higher than any string value, and any string value is always considered to be higher than any list. Lists are compared in dictionary order, i.e. list elements are compared pairwise in ascending order from the start of the list to the end. `max(null)` returns `null`.

```
SELECT *  
FROM cypher('graph_name', $$  
    MATCH (n:Person)  
    RETURN max(n.age)  
$$) as (max_age agtype);
```

```
max_age  
-----  
44  
(1 row)
```

The highest of all the values in the property `age` is returned.

`stDev(expression variadic "any")` returns agtype float

`stDev()` returns the standard deviation for the given value over a group. It uses a standard two-pass method, with  $N - 1$  as the denominator, and should be used when taking a sample of the population for an unbiased estimate. When the standard deviation of the entire population is being calculated, [stDevP](#) should be used. Any `null` values are excluded from the calculation. `stDev(null)` returns 0.0 (zero).

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n:Person)
    RETURN stDev(n.age)
$$) as (stdev_age agtype);
```

```
    stdev_age
-----
 15.716233645501712
(1 row)
```

The standard deviation of the values in the property `age` is returned.

`stDevP(expression variadic "any")` returns agtype float

`stDevP()` returns the standard deviation for the given value over a group. It uses a standard two-pass method, with  $N$  as the denominator, and should be used when calculating the standard deviation for an entire population. When the standard deviation of only a sample of the population is being calculated, [stDev](#) should be used. Any `null` values are excluded from the calculation. `stDevP(null)` returns 0.0 (zero).

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n:Person)
    RETURN stDevP(n.age)
$$) as (stdevp_age agtype);
```

```
    stdevp_age
-----
 12.832251036613439
(1 row)
```

The population standard deviation of the values in the property `age` is returned.

`percentileCont(expression agtype, percentile agtype)` returns agtype float

`percentileCont()` returns the percentile of the given value over a group, with a percentile from 0.0 to 1.0. It uses a linear interpolation method, calculating a weighted average between two values if the desired percentile lies between them. For nearest values using a rounding method, see [percentileDisc](#). Any `null` values are excluded from the calculation. `percentileCont(null, percentile)` returns `null`.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n:Person)
    RETURN percentileCont(n.age, 0.4)
$$) as (percentile_cont_age agtype);
```

```
    percentile_cont_age
-----
                29.0
```

(1 row)

The 40th percentile of the values in the property `age` is returned, calculated with a weighted average. In this case, 0.4 is the median, or 40th percentile.

`percentileDisc(expression agtype, percentile agtype)` returns `agtype float`

`percentileDisc()` returns the percentile of the given value over a group, with a percentile from 0.0 to 1.0. It uses a rounding method and calculates the nearest value to the percentile. For interpolated values, see [percentileCont](#). Any null values are excluded from the calculation. `percentileDisc(null, percentile)` returns `null`.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n:Person)
    RETURN percentileDisc(n.age, 0.5)
$$) as (percentile_disc_age agtype);
```

```
percentile_disc_age
-----
33.0
(1 row)
```

The 50th percentile of the values in the property `age` is returned.

`count(expression agtype)` returns `agtype integer`

`count()` returns the number of values or records, and appears in two variants:

- `count(*)` returns the number of matching records.
- `count(expr)` returns the number of non-null values returned by an expression.

`count(*)` includes records returning `null`. `count(expr)` ignores `null` values. `count(null)` returns 0 (zero). `count(*)` can be used to return the number of nodes; for example, the number of nodes connected to some node `n`.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n {name: 'A'})-[]->(x)
    RETURN n.age, count(*)
$$) as (age agtype, number_of_people agtype);
```

```
age | number_of_people
-----+-----
13  | 3
(1 row)
```

The `age` property of the start node `n` (with a name value of "A") and the number of nodes related to `n` are returned.

`count(*)` can be used to group and count relationship types, returning the number of relationships of each type.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n {name: 'A'})-[r]->()
    RETURN type(r), count(*)
$$) as (label agtype, count agtype);
```

```
label | count
-----+-----
"KNOWS" | 3
```

(1 row)

The relationship type and the number of relationships with that type are returned.

Instead of simply returning the number of records with `count(*)`, it may be more useful to return the actual number of values returned by an expression.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n {name: 'A'})-[]->(x)
    RETURN count(x)
$$) as (count agtype);
```

```
count
-----
3
(1 row)
```

The number of nodes connected to the start node `n` is returned.

`count(expression)` can be used to return the number of non-null values returned by the expression.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (n:Person)
    RETURN count(n.age)
$$) as (count agtype);
```

```
count
-----
3
(1 row)
```

The number of nodes with the label `Person` that have a non-null value for the `age` property is returned.

In the following example we are trying to find all our friends of friends, and count them. The first **aggregate function**, `count(DISTINCT friend_of_friend)`, will only count a `friend_of_friend` once, as `DISTINCT` removes the duplicates. The second aggregate function, `count(friend_of_friend)`, will consider the same `friend_of_friend` multiple times.

```
SELECT *
FROM cypher('graph_name', $$
    MATCH (me:Person)-[]->(friend:Person)-[]->(friend_of_friend:Person)
    WHERE me.name = 'A'
    RETURN count(DISTINCT friend_of_friend), count(friend_of_friend)
$$) as (friend_of_friends_distinct agtype, friend_of_friends agtype);
```

```
friend_of_friends_distinct | friend_of_friends
-----+-----
1                          | 2
(1 row)
```

Both B and C know D and thus D will get counted twice when not using `DISTINCT`.

`avg(expression agtype)` returns `agtype integer`

`avg()` returns the average of a set of numeric values. Any `null` values are excluded from the calculation. `avg(null)` returns `null`.

```
SELECT *
FROM cypher('graph_name', $$
```

```
MATCH (n:Person)
RETURN avg(n.age)
$$) as (avg_age agtype);
```

```
avg_age
-----
30.0
(1 row)
```

The average of all the values in the property `age` is returned.

`sum(expression agtype)` returns `agtype float`

`sum()` returns the sum of a set of numeric values. Any `null` values are excluded from the calculation.  
`sum(null)` returns `null`.

```
SELECT *
FROM cypher('graph_name', $$
MATCH (n:Person)
RETURN sum(n.age)
$$) as (total_age agtype);
```

```
total_age
-----
90
(1 row)
```

The sum of all the values in the property `age` is returned.

## F.3.28. User-Defined Functions

Users may add custom functions to `apache_age`. When using Cypher functions, all function calls with a Cypher query use the default namespace of: `ag_catalog`. However, if a user wants to use a function outside of this namespace, they may do so by adding the namespace before the function name.

**Syntax:** `namespace_name.function_name`

```
SELECT *
FROM cypher('graph_name', $$
RETURN pg_catalog.sqrt(25)
$$) as (result agtype);
```

```
result
-----
25
(1 row)
```

## F.3.29. `apache_age` Beyond Cypher

All queries so far have followed the same pattern: a `SELECT` clause followed by a single Cypher call in the `FROM` clause. However, a Cypher query can be used in many other ways. This section highlights some more advanced ways of using the Cypher call within a more complex SQL/Cypher Hybrid Query.

### F.3.29.1. Using Cypher in a CTE Expression

There are no restrictions to using Cypher with CTEs ([Common Table Expression](#)).

```
WITH graph_query as (
  SELECT *
    FROM cypher('graph_name', $$
      MATCH (n)
```

```
    RETURN n.name, n.age
    $$) as (name agtype, age agtype)
)
SELECT * FROM graph_query;
```

| name     | age |
|----------|-----|
| "Andres" | 36  |
| "Tobias" | 25  |
| "Peter"  | 35  |

(3 rows)

### F.3.29.2. Using Cypher in a Join expression

A Cypher query can be part of a `JOIN` clause.

#### Note

Cypher queries using the `CREATE`, `SET`, `REMOVE` clauses cannot be used in SQL queries with joins, as they affect the Postgres Pro transaction system. One possible solution is to protect the query with CTEs.

```
SELECT id,
       graph_query.name = t.name as names_match,
       graph_query.age = t.age as ages_match
FROM schema_name.sql_person AS t
JOIN cypher('graph_name', $$
    MATCH (n:Person)
    RETURN n.name, n.age, id(n)
$$) as graph_query(name agtype, age agtype, id agtype)
ON t.person_id = graph_query.id;
```

| id | names_match | ages_match |
|----|-------------|------------|
| 1  | True        | True       |
| 2  | False       | True       |
| 3  | True        | False      |

(3 rows)

### F.3.29.3. Cypher in SQL Expressions

Cypher cannot be used in an expression, the query must exist in the `FROM` clause of a query. However, if the Cypher query is placed in a subquery, it will behave as any SQL style query.

#### F.3.29.3.1. Using Cypher with =

When writing a Cypher query that is known to return one column and one row, the `=` comparison operator may be used.

```
SELECT t.name FROM schema_name.sql_person AS t
where t.name = (
    SELECT a
    FROM cypher('graph_name', $$
        MATCH (v)
        RETURN v.name
    $$) as (name varchar(50))
    ORDER BY name
    LIMIT 1);
```

| name     | age |
|----------|-----|
| "Andres" | 36  |

(1 rows)

#### F.3.29.3.2. Working with Postgres Pro IN Clause

When writing a Cypher query that is known to return one column but may have multiple rows, the `IN` operator may be used.

```
SELECT t.name, t.age FROM schema_name.sql_person as t
where t.name in (
    SELECT *
    FROM cypher('graph_name', $$
        MATCH (v:Person)
        RETURN v.name
    $$) as (a agtype));
```

| name     | age |
|----------|-----|
| "Andres" | 36  |
| "Tobias" | 25  |
| "Peter"  | 35  |

(3 rows)

#### F.3.29.3.3. Working with Postgres Pro EXISTS Clause

When writing a Cypher query that may have more than one column and row returned, the `EXISTS` operator may be used.

```
SELECT t.name, t.age
FROM schema_name.sql_person as t
WHERE EXISTS (
    SELECT *
    FROM cypher('graph_name', $$
        MATCH (v:Person)
        RETURN v.name, v.age
    $$) as (name agtype, age agtype)
    WHERE name = t.name AND age = t.age
);
```

| name     | age |
|----------|-----|
| "Andres" | 36  |
| "Tobias" | 25  |
| "Peter"  | 35  |

(3 rows)

#### F.3.29.3.4. Querying Multiple Graphs

There is no restriction to the number of graphs an SQL statement can query. Users may query multiple graphs simultaneously.

```
SELECT graph_1.name, graph_1.age, graph_2.license_number
FROM cypher('graph_1', $$
    MATCH (v:Person)
    RETURN v.name, v.age
$$) as graph_1(col_1 agtype, col_2 agtype, col_3 agtype)
JOIN cypher('graph_2', $$
    MATCH (v:Doctor)
    RETURN v.name, v.license_number
```

```
$$) as graph_2(name agtype, license_number agtype)
ON graph_1.name = graph_2.name
```

```
name      | age | license_number
-----+-----+-----
"Andres"   | 36  | 1234567890
(1 rows)
```

### F.3.29.4. Prepared Statements

Cypher can run a read query within a prepared statement. When using parameters with stored procedures, an SQL parameter must be placed in the Cypher function call. See [The apache\\_age Query Format](#) for details.

A Cypher parameter is in the format of a "\$" followed by an identifier. Unlike Postgres Pro parameters, Cypher parameters start with a letter, followed by an alphanumeric string of arbitrary length. Example:  
*\$parameter\_name*

Preparing prepared statements in Cypher is an extension of Postgres Pro stored procedure system. Use the `PREPARE` clause to create a query with the Cypher function call in it. Do not place Postgres Pro style parameters in the Cypher query call, instead place Cypher parameters in the query and place a Postgres Pro parameter as the third argument in the Cypher function call.

```
PREPARE cypher_stored_procedure(agtype) AS
SELECT *
FROM cypher('expr', $$
    MATCH (v:Person)
    WHERE v.name = $name //Cypher parameter
    RETURN v
$$, $1) //An SQL Parameter must be placed in the Cypher function call
AS (v agtype);
```

When executing the prepared statement, place an `agtype` map with the parameter values where the Postgres Pro parameter in the Cypher function call is. The value must be an `agtype` map or an error will be thrown. Exclude the \$ for parameter names.

```
EXECUTE cypher_prepared_statement('{name': 'Tobias'});
```

### F.3.29.5. PL/pgSQL Functions

Cypher commands can be run in [PL/pgSQL](#) functions without restriction.

```
SELECT *
FROM cypher('imdb', $$
    CREATE (toby:actor {name: 'Toby Maguire'}),
           (tom:actor {name: 'Tom Holland'}),
           (willam:actor {name: 'Willam Dafoe'}),
           (robert:actor {name: 'Robert Downey Jr'}),
           (spiderman:movie {title: 'Spiderman'}),
           (no_way_home:movie {title: 'Spiderman: No Way Home'}),
           (homecoming:movie {title: 'Spiderman: Homecoming'}),
           (ironman:movie {title: 'Ironman'}),
           (tropic_thunder:movie {title: 'Tropic Thunder'}),
           (toby)-[:acted_in {role: 'Peter Parker', alter_ego: 'Spiderman'}]->(spiderman),
           (willam)-[:acted_in {role: 'Norman Osborn', alter_ego: 'Green Goblin'}]-
>(spiderman),
           (toby)-[:acted_in {role: 'Toby Maguire'}]->(tropic_thunder),
           (robert)-[:acted_in {role: 'Kirk Lazarus'}]->(tropic_thunder),
           (robert)-[:acted_in {role: 'Tony Stark', alter_ego: 'Ironman'}]->(homecoming),
           (tom)-[:acted_in {role: 'Peter Parker', alter_ego: 'Spiderman'}]->(homecoming),
```

```
(tom)-[:acted_in {role: 'Peter Parker', alter_ego: 'Spiderman'}]-
>(no_way_home),
(toby)-[:acted_in {role: 'Peter Parker', alter_ego: 'Spiderman'}]-
>(no_way_home),
(willam)-[:acted_in {role: 'Norman Osborn', alter_ego: 'Green Goblin'}]-
>(no_way_home)
$$) AS (a agtype);
```

The example of function creation is shown below.

```
CREATE OR REPLACE FUNCTION get_all_actor_names()
RETURNS TABLE(actor agtype)
LANGUAGE plpgsql
AS $BODY$
BEGIN
    LOAD 'age';
    SET search_path TO ag_catalog;

    RETURN QUERY
    SELECT *
    FROM ag_catalog.cypher('imdb', $$
        MATCH (v:actor)
        RETURN v.name
    $$) AS (a agtype);
END
$BODY$;
```

Execute the query:

```
SELECT * FROM get_all_actor_names();

   actor
-----
 "Toby Maguire"
 "Tom Holland"
 "Willam Dafoe"
 "Robert Downey Jr"
(4 rows)
```

### Note

It is recommended to add the `LOAD 'age'` command and setting the `search_path` to the function declaration to ensure that the `CREATE FUNCTION` command works consistently.

#### F.3.29.5.1. Dynamic Cypher Example

```
CREATE OR REPLACE FUNCTION get_actors_who_played_role(role agtype)
RETURNS TABLE(actor agtype, movie agtype)
LANGUAGE plpgsql
AS $function$
DECLARE sql VARCHAR;
BEGIN
    load 'age';
    SET search_path TO ag_catalog;

    sql := format('
    SELECT *
    FROM cypher(''imdb'', $$
```

Additional Supplied Modules  
and Extensions Shipped in  
postgrespro-ent-14-contrib

---

```
MATCH (actor)-[:acted_in {role: %s}]->(movie:movie)
RETURN actor.name, movie.title
$$) AS (actor agtype, movie agtype);
', role);
```

```
RETURN QUERY EXECUTE sql;
```

```
END
```

```
$function$;
```

```
SELECT * FROM get_actors_who_played_role('"Peter Parker"');
```

| actor          | movie                    |
|----------------|--------------------------|
| "Toby Maguire" | "Spiderman: No Way Home" |
| "Toby Maguire" | "Spiderman"              |
| "Tom Holland"  | "Spiderman: Homecoming"  |
| "Tom Holland"  | "Spiderman: No Way Home" |

(4 rows)

### F.3.29.6. SQL in Cypher

apache\_age does not support SQL being directly written in Cypher. However, with [user-defined functions](#) you can write SQL queries and call them in a Cypher command.

#### Note

This applies to void and scalar-value functions only. Set returning functions are not currently supported.

Create a function:

```
CREATE OR REPLACE FUNCTION public.get_event_year(name agtype) returns agtype AS $$
    SELECT year::agtype
    FROM history AS h
    WHERE h.event_name = name::text
    LIMIT 1;
$$ LANGUAGE sql;
```

```
SELECT * FROM cypher('graph_name', $$
    MATCH (e:event)
    WHERE e.year < public.get_event_year(e.name)
    RETURN e.name
    $$) as (n agtype);
```

| n                 |
|-------------------|
| "Apache Con 2021" |

(1 row)

## F.4. aqo

The aqo module is a Postgres Pro Enterprise extension for cost-based query optimization. Using machine learning methods, more precisely, a modification of the k-NN algorithm, aqo improves cardinality estimation, which can optimize execution plans and, consequently, speed up query execution.

The aqo module can collect statistics on all the executed queries, excluding the queries that access system relations. The collected statistics is classified by query class. If the queries differ in their constants only, they belong to the same class. For each query class, aqo stores the cardinality quality, planning

time, execution time, and execution statistics for machine learning. Based on this data, aqo builds a new query plan and uses it for the next query of the same class. aqo test runs have shown significant performance improvements for complex queries.

### Important

Query optimization using the aqo module is not supported on standby.

aqo saves all the learning data ([aqo\\_data](#)), queries ([aqo\\_query\\_texts](#)), query settings ([aqo\\_queries](#)), and query execution statistics ([aqo\\_query\\_stat](#)) to files. When aqo starts, it loads this data to shared memory. You can access aqo data through functions and views.

### Warning

Be aware that aqo may not work correctly right after extension upgrades that change its kernel and after Postgres Pro upgrades. Therefore, after each Postgres Pro upgrade, call `aqo_reset()` and run `DROP EXTENSION aqo`. However, after Postgres Pro minor release upgrades to versions to 13.11/14.8/15.3 or higher a call to `aqo_reset()` is not needed as aqo is reset automatically if required.

After a minor release upgrade, also run `ALTER EXTENSION aqo UPDATE` and keep in mind that aqo downgrade is impossible.

In the event of an automatic aqo reset or manually calling `aqo_reset()`, all the machine learning data gets lost, and new learning will be needed for future aqo use. Therefore, if some data, such as query texts, may help in aqo learning, back up this data in advance.

## F.4.1. Installation and Setup

The aqo extension is included into Postgres Pro Enterprise. Once you have Postgres Pro Enterprise installed, complete the following steps to enable aqo:

1. Add aqo to the [shared\\_preload\\_libraries](#) parameter in the `postgresql.conf` file:

```
shared_preload_libraries = 'aqo'
```

The aqo library must be preloaded at the server startup, since adaptive query optimization needs to be enabled per cluster.

2. Create the aqo extension using the following query:

```
CREATE EXTENSION aqo;
```

Once the extension is created, you can start optimizing queries.

The command

```
DROP EXTENSION aqo;
```

will only remove aqo interface at the cluster level. aqo will still be running on all the backends while it is listed in `shared_preload_libraries` and at the server restart, will continue working in the operation mode specified in `postgresql.conf`. Besides, aqo will retain its internal state after consequent execution of `DROP EXTENSION -> CREATE EXTENSION`.

To remove all the data from the aqo storage, including the collected statistics, call `aqo_reset()`:

```
SELECT aqo_reset();
```

To actually disable aqo at the cluster level, do the following:

```
ALTER SYSTEM SET aqo.mode = 'disabled';
```

```
SELECT pg_reload_conf();  
DROP EXTENSION aqo;
```

If you do not want aqo to be loaded at the server restart, remove the line

```
shared_preload_libraries = 'aqo'
```

from the `postgresql.conf` file.

#### F.4.1.1. Configuration

With the default operation mode (`controlled`), aqo does not affect query performance. Depending on your database usage model, you should choose between the following modes:

- `intelligent` — this mode auto-tunes your queries based on statistics collected per query class. See the description of the `auto_tuning` flag of the [aqo\\_queries](#) view for more details.
- `forced` — this mode collects statistics for all queries altogether without any classification.
- `controlled` — this mode uses the default planner for all new queries, but continues using the previously specified planning settings for already known query classes, if any.
- `learn` — this mode collects statistics on all the executed queries and updates the data for query classes without auto-tuning queries.
- `frozen` — this mode reads the collected statistics for already known query classes but does not collect any new data. You can use this mode to reduce the impact of aqo on query planning and execution.
- `disabled` — this mode disables aqo for all queries, even for the known query classes. The collected statistics and aqo settings are saved and can be used in the future. You can use this mode to temporarily disable aqo without losing the collected statistics and configuration.

To dynamically change the aqo mode in your current session, run the following command:

```
ALTER SYSTEM SET aqo.mode = 'mode';  
SELECT pg_reload_conf();
```

where `mode` is the name of the operation mode to use.

## F.4.2. Usage

### F.4.2.1. Choosing Operation Mode for Query Optimization

If you often run queries of the same class, for example, your application limits the number of possible query classes, you can use the `intelligent` mode to improve planning for these queries. In this mode, aqo analyzes each query execution and stores statistics. Statistics on queries of different classes is stored separately. If performance is not improved after 50 iterations, the aqo extension falls back to the default query planner.

#### Note

You can view the current query plan using the standard Postgres Pro `EXPLAIN` command with the `ANALYZE` option. For details, see the [Section 14.1](#).

Since the `intelligent` mode tries to learn separately for different query classes, aqo may fail to provide performance improvements if queries in the workload are of multiple different classes or if the classes of the queries in the workload are constantly changing. For such workloads, reset the aqo extension to the `controlled` mode, or try using the `forced` mode.

In the `forced` mode, aqo does not classify the collected statistics by query classes and tries to optimize all queries together. Therefore, [aqo\\_query\\_texts](#), [aqo\\_queries](#) and [aqo\\_query\\_stat](#) views do not get updated. Machine learning data collected in any other modes is inapplicable for the `forced` mode and vice versa. This mode can help you optimize workloads with multiple different query classes, and it consumes less memory than the `intelligent` mode. However, since the `forced` mode lacks intelligent tuning, per-

formance may decrease for some queries. If you see performance issues in this mode, switch aqo to the `controlled` mode.

In the `controlled` mode, aqo does not collect statistics for new query classes, so they will not be optimized. For known query classes, aqo will continue collecting statistics and using optimized planning algorithms. So use the `controlled` mode only after aqo learned in the `learn` or `intelligent` mode. As there are no query classes in the `forced` mode, switching from it to the `controlled` mode actually means disabling aqo.

The `learn` mode collects statistics from all the executed queries and updates the data for query classes. This mode is similar to the `intelligent` mode, except that it does not provide intelligent tuning.

If you want to reduce the impact of aqo on query planning and execution, you can use it in the `frozen` mode. In this mode, aqo only reads the collected statistics for already known query classes but does not collect any new data.

Switching to the `disabled` mode is the only way to actually disable aqo without losing the statistics and aqo settings, which are saved and can be used in the future. Queries in this mode will be executed as though there were no aqo at all.

#### F.4.2.2. Fine-Tuning aqo

You must have superuser rights to access aqo views and configure advanced query settings.

When run in the `intelligent` or `learn` mode, aqo assigns a unique hash value to each query class to separate the collected statistics. If you switch to the `forced` mode, the statistics for all untracked query classes is stored in a common query class with hash 0. You can view all the processed query classes and their corresponding hash values in the `aqo_query_texts` view:

```
SELECT * FROM aqo_query_texts;
```

To find out the class, that is, hash, of a query and aqo mode, enable `aqo.show_hash` and `aqo.show_details` environment variables and execute the query. The output will contain something like this:

```
...
Planning Time: 23.538 ms
...
Execution Time: 249813.875 ms
...
Using aqo: true
...
AQO mode: LEARN
...
Query hash: -2439501042637610315
```

Each query class has an associated separate space, called *feature space*, in which the statistics for this query class is collected. Each feature space has associated *feature subspaces*, where the information about selectivity and cardinality for each query plan node is collected.

Each query class has its own optimization settings. These settings are shown in the `aqo_queries` view:

```
SELECT * FROM aqo_queries;
```

The settings available are listed in the [aqo\\_queries View](#) table.

You can manually change these settings to adjust optimization for a particular query class. For example:

```
-- Add a new query class into the aqo_queries view:

SET aqo.mode='intelligent';
SELECT * FROM a, b WHERE a.id=b.id;
SET aqo.mode='controlled';
```

```
-- Disable auto_tuning, enable both learn_aqo and use_aqo
-- for this query class:

SELECT count(*) FROM (SELECT queryid FROM aqo_queries) AS q1,
  LATERAL aqo_queries_update(q1.queryid, NULL, true, true, false) AS q2
WHERE queryid = (SELECT queryid FROM aqo_query_texts
  WHERE query_text LIKE 'SELECT * FROM a, b WHERE a.id=b.id;');

-- Run EXPLAIN ANALYZE until the plan changes:

EXPLAIN ANALYZE SELECT * FROM a, b WHERE a.id=b.id;
EXPLAIN ANALYZE SELECT * FROM a, b WHERE a.id=b.id;

-- Disable learning to stop statistics collection
-- and use the optimized plan:

SELECT count(*) FROM (SELECT queryid FROM aqo_queries) AS q1,
  LATERAL aqo_queries_update(q1.queryid, NULL, false, true, false) AS q2
WHERE queryid = (SELECT queryid FROM aqo_query_texts
  WHERE query_text LIKE 'SELECT * FROM a, b WHERE a.id=b.id;');
```

To stop intelligent tuning for a particular query class, disable the `auto_tuning` setting:

```
SELECT count(*) FROM (SELECT queryid FROM aqo_queries) AS q1,
  LATERAL aqo_queries_update(q1.queryid, NULL, true, true, false) AS q2
WHERE queryid = 'hash');
```

where *hash* is the hash value for this query class. As a result, `aqo` disables automatic change of the `learn_aqo` and `use_aqo` settings.

To disable further learning for a particular query class, use the following command:

```
SELECT count(*) FROM (SELECT queryid FROM aqo_queries) AS q1,
  LATERAL aqo_queries_update(q1.queryid, NULL, false, true, false) AS q2
WHERE queryid = 'hash');
```

where *hash* is the hash value for this query class.

To fully disable `aqo` for all queries and use the default Postgres Pro query planner, run:

```
SELECT count(*) FROM (SELECT queryid FROM aqo_queries) AS q1,
  LATERAL aqo_queries_update(q1.queryid, NULL, false, false, false) AS q2
WHERE queryid IN (SELECT queryid FROM aqo_query_texts);
```

## F.4.3. Reference

### F.4.3.1. Configuration Parameters

`aqo.mode` (text)

Defines the `aqo` operation mode. Possible values are listed in [Section F.4.1.1](#).

Default: `controlled`.

`aqo.show_hash` (boolean)

Show a hash value that is computed from a query tree and uniquely identifies the class of queries or class of plan nodes. Starting with Postgres Pro 14, `aqo` uses the native query ID to identify a query class for consistency with other extensions, such as [pg\\_stat\\_statements](#). So, the query ID can be taken from the `Query Identifier` field in `EXPLAIN ANALYZE` output of a query.

Default: `off`.

`aqo.show_details` (boolean)

Add some details to `EXPLAIN` output of a query, such as the prediction or feature-subspace hash, and show some additional aqo-specific on-screen information.

Default: `off`.

`aqo.join_threshold` (integer)

Ignore queries that contain smaller number of joins, which means that statistics for such queries will not be collected.

Default: 3.

`aqo.statement_timeout` (integer)

Defines the initial value of the *smart statement timeout*, in milliseconds, which is needed to limit the execution time when manually training aqo on special queries with a poor cardinality forecast. aqo can dynamically change the value of the smart statement timeout during this training. When the cardinality estimation error on nodes exceeds 0.1, the value of `aqo.statement_timeout` is automatically incremented exponentially, but remains not greater than `statement_timeout`.

Default: 0.

`aqo.force_collect_stat` (boolean)

Gather statistics on query executions even in the `disabled` mode. Although no predictions are made, some overhead will be added.

Default: `off`.

`aqo.dsm_size_max` (integer)

Defines the maximum size of dynamic shared memory, in MB, that aqo can allocate to store learning data. When this number is exceeded, an attempt to load the `aqo_data` view will fail with “out of memory” error.

Default: 100.

`aqo.fs_max_items` (integer)

Defines the maximum number of feature spaces that aqo can operate with. When this number is exceeded, learning on new query classes will no longer occur, and they will not appear in the views accordingly.

Default: 10000.

`aqo.fss_max_items` (integer)

Defines the maximum number of feature subspaces that aqo can operate with. When this number is exceeded, the selectivity and cardinality for new query plan nodes will no longer be collected, and new feature subspaces will not appear in the `aqo_data` view accordingly.

Default: 100000.

`aqo.wide_search` (boolean)

Enables searching neighbors with the same feature subspace among different query classes.

Default: `off`.

`aqo.querytext_max_size` (integer)

Defines the maximum size of the query in the `aqo_query_texts` view.

Default: 1000.

---

`aqo.min_neighbors_for_predicting` (integer)

Defines the minimum number of neighbors needed for the cardinality prediction. If there are fewer of them, aqo will not make any prediction.

Default: 3.

`aqo.predict_with_few_neighbors` (boolean)

Enables aqo to make predictions with fewer neighbors than were found.

Default: on.

## F.4.3.2. Views

### F.4.3.2.1. `aqo_query_texts`

The `aqo_query_texts` view classifies all the query classes processed by aqo. For each query class, the view shows the text of the first analyzed query of this class.

**Table F.8. `aqo_query_texts` View**

| Column Name             | Description                                                                                     |
|-------------------------|-------------------------------------------------------------------------------------------------|
| <code>queryid</code>    | Stores the query ID, that is, the feature-space hash, that uniquely identifies the query class. |
| <code>query_text</code> | Provides the text of the first analyzed query of the given class.                               |

### F.4.3.2.2. `aqo_queries`

The `aqo_queries` view shows optimization settings for different query classes.

**Table F.9. `aqo_queries` View**

| Setting                  | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|--------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>queryid</code>     | Stores the query ID that uniquely identifies the query class.                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| <code>learn_aqo</code>   | Enables statistics collection for this query class.                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| <code>use_aqo</code>     | Enables the aqo cardinality prediction for the next execution of this query class. If the cost estimation model is inaccurate, this may slow down query execution.                                                                                                                                                                                                                                                                                                                                                              |
| <code>fspace_hash</code> | Provides a unique identifier of the separate space in which the statistics for this query class is collected. By default, <code>fspace_hash</code> is equal to <code>queryid</code> . You can change this setting to a different <code>queryid</code> to optimize different query classes together. It may decrease the amount of memory for models and even improve query execution performance. However, changing this setting may cause unexpected aqo behavior, so make sure to use it only if you know what you are doing. |
| <code>auto_tuning</code> | <p>Shows whether aqo can dynamically change <code>use_aqo</code> and <code>learn_aqo</code> settings for this query class. By default, auto-tuning is only enabled in the intelligent mode.</p> <p>In more detail, when <code>auto_tuning</code> is on, if for several successive executions of a query for which</p>                                                                                                                                                                                                           |

| Setting                             | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
|-------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                     | <p><code>use_aqo</code> is off, the cardinality error remains sufficiently small and stable, <code>aqo</code> turns on <code>use_aqo</code>.</p> <p>For queries with <code>learn_aqo = true</code> (it is so for new queries), several first executions are done both using <code>aqo</code> and without it. The faster the query is executed compared to the execution with the standard planner, the more likely <code>aqo</code> will be used for the next query execution. If after a certain number of executions the execution time with <code>aqo</code> appears to be worse than with the standard planner, <code>aqo</code> will never be used for this query class: <code>auto_tuning</code>, <code>use_aqo</code> and <code>learn_aqo</code> are set to off.</p> |
| <code>smart_timeout</code>          | Shows the value of smart statement timeout for this query class.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| <code>count_increase_timeout</code> | Shows how many times the smart statement timeout increased for this query class.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |

#### F.4.3.2.3. `aqo_data`

The `aqo_data` view shows machine learning data for cardinality estimation refinement. To forget all the collected statistics for a particular query class, you can delete all rows from `aqo_data` with the corresponding `fs`.

**Table F.10. `aqo_data` View**

| Data                     | Description                                                                                                                                                                                                                                                                                                                          |
|--------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>fs</code>          | Feature-space hash.                                                                                                                                                                                                                                                                                                                  |
| <code>fss</code>         | Feature-subspace hash.                                                                                                                                                                                                                                                                                                               |
| <code>nfeatures</code>   | Feature-subspace size for the query plan node.                                                                                                                                                                                                                                                                                       |
| <code>features</code>    | Logarithm of the selectivity which the cardinality prediction is based on.                                                                                                                                                                                                                                                           |
| <code>targets</code>     | Cardinality logarithm for the query plan node.                                                                                                                                                                                                                                                                                       |
| <code>reliability</code> | <p>Equals:</p> <ul style="list-style-type: none"> <li>1 — indicates data obtained after normal execution of a query</li> <li>0.1 — indicates data obtained from a partially executed node (not needed as unreliable)</li> <li>0.9 — indicates data obtained from a finished node, but from a partially executed statement</li> </ul> |
| <code>oids</code>        | List of IDs of tables that were involved in the prediction for this node.                                                                                                                                                                                                                                                            |

#### F.4.3.2.4. `aqo_query_stat`

The `aqo_query_stat` view shows statistics on query execution, by query class. The `aqo` extension uses this data when the `auto_tuning` option is enabled for a particular query class.

**Table F.11. `aqo_query_stat` View**

| Data                                 | Description                                                   |
|--------------------------------------|---------------------------------------------------------------|
| <code>execution_time_with_aqo</code> | Execution time for queries run with <code>aqo</code> enabled. |

| Data                                       | Description                                                                 |
|--------------------------------------------|-----------------------------------------------------------------------------|
| <code>execution_time_without_aqo</code>    | Execution time for queries run with aqo disabled.                           |
| <code>planning_time_with_aqo</code>        | Planning time for queries run with aqo enabled.                             |
| <code>planning_time_without_aqo</code>     | Planning time for queries run with aqo disabled.                            |
| <code>cardinality_error_with_aqo</code>    | Cardinality estimation error in the selected query plans with aqo enabled.  |
| <code>cardinality_error_without_aqo</code> | Cardinality estimation error in the selected query plans with aqo disabled. |
| <code>executions_with_aqo</code>           | Number of queries run with aqo enabled.                                     |
| <code>executions_without_aqo</code>        | Number of queries run with aqo disabled.                                    |

### F.4.3.3. Functions

aqo adds several functions to Postgres Pro catalog.

#### F.4.3.3.1. Storage Management Functions

#### Important

**Functions** `aqo_queries_update`, `aqo_query_texts_update`, `aqo_query_stat_update`, and `aqo_data_update` modify data files underlying aqo views. Therefore, call these functions only if you understand the logic of adaptive query optimization.

`aqo_cleanup()` → setof integer

Removes data related to query classes that are linked (may be partially) with removed relations. Returns the number of removed feature spaces (classes) and feature subspaces. Insensitive to removing other objects.

`aqo_enable_class(queryid bigint)` → void

Sets `learn_aqo`, `use_aqo` and `auto_tuning` (only in the intelligent mode) to true for a given query class.

`aqo_disable_class(queryid bigint)` → void

Sets `learn_aqo`, `use_aqo` and `auto_tuning` (only in the intelligent mode) to false for a given query class.

`aqo_drop_class(queryid bigint)` → integer

Removes all data related to a given query class from the aqo storage. Returns the number of records removed from the aqo storage.

`aqo_reset()` → bigint

Removes data from the aqo storage: machine learning data, query texts, statistics and query class preferences. Returns the number of records removed from the aqo storage.

`aqo_queries_update(queryid bigint, fs bigint, learn_aqo boolean, use_aqo boolean, auto_tuning boolean)` → boolean

Assigns new values to the following settings in the [aqo\\_queries](#) view for a given query class: `fspace_hash`, `learn_aqo`, `use_aqo` and `auto_tuning`. NULL value means “leave as is”.

`aqo_query_texts_update(queryid bigint, query_text text)` → boolean

Updates or inserts a record in a data file underlying the [aqo\\_query\\_texts](#) view for a given `queryid`.

Additional Supplied Modules  
and Extensions Shipped in  
postgrespro-ent-14-contrib

---

`aqo_query_stat_update (queryid bigint, execution_time_with_aqo double precision[], execution_time_without_aqo double precision[], planning_time_with_aqo double precision[], planning_time_without_aqo double precision[], cardinality_error_with_aqo double precision[], cardinality_error_without_aqo double precision[], executions_with_aqo bigint[], executions_without_aqo bigint[]) → boolean`

Updates or inserts a record in a data file underlying the [aqo\\_query\\_stat](#) view for a given *queryid*.

`aqo_data_update (fs bigint, fss integer, nfeatures integer, features double precision[][], targets double precision[], reliability double precision[], oids oid[]) → boolean`

Updates or inserts a record in a data file underlying the [aqo\\_data](#) view for given *fs* and *fss*.

#### F.4.3.3.2. Memory Management Functions

`aqo_memory_usage () → setof record`

Displays sizes of aqo memory contexts and hash tables.

#### F.4.3.3.3. Analytics Functions

`aqo_cardinality_error (controlled boolean) → setof record`

Shows the cardinality error for each query class. If *controlled* is true, shows the error of the last execution with aqo enabled. If *controlled* is false, returns the average cardinality error for all logged executions with aqo disabled.

`aqo_execution_time (controlled boolean) → setof record`

Shows the execution time for each query class. If *controlled* is true, shows the execution time of the last execution with aqo enabled. If *controlled* is false, returns the average execution time for all logged executions with aqo disabled.

### F.4.4. Examples

#### Example F.1. Learning on a Query

Consider optimization of a query using aqo.

When the query is executed for the first time, it is missing in tables underlying aqo views. So there is no data for predicting with aqo for each plan node, and “AQO not used” lines appear in the EXPLAIN output:

```
postgres=# EXPLAIN (ANALYZE, SUMMARY OFF, TIMING OFF) select count(*) from score join
course on score.cno=course.cno join student on score.sno=student.sno where degree<90
and test_preparation = 0;
```

QUERY PLAN

```
-----
Aggregate  (cost=308.28..308.29 rows=1 width=8) (actual rows=1 loops=1)
  AQO not used, fss=0
  -> Hash Join  (cost=124.80..299.47 rows=3526 width=0) (actual rows=3649 loops=1)
    AQO not used, fss=2128507884
    Hash Cond: (score.sno = student.sno)
    -> Hash Join  (cost=16.30..181.70 rows=3526 width=4) (actual rows=3649
loops=1)
      AQO not used, fss=-303037802
      Hash Cond: (score.cno = course.cno)
      -> Seq Scan on score  (cost=0.00..156.00 rows=3526 width=8) (actual
rows=3649 loops=1)
        AQO not used, fss=-636613046
        Filter: ((degree < 90) AND (test_preparation = 0))
        Rows Removed by Filter: 1351
      -> Hash  (cost=12.80..12.80 rows=280 width=4) (actual rows=10 loops=1)
        Buckets: 1024  Batches: 1  Memory Usage: 9kB
```

Additional Supplied Modules  
and Extensions Shipped in  
postgrespro-ent-14-contrib

```

-> Seq Scan on course (cost=0.00..12.80 rows=280 width=4)

(24 rows)

```

If there is no information on a certain node in the `aqo_data` view, aqo will add the appropriate record there for future learning and predictions except for nodes with `fss=0` in the `EXPLAIN` output. As each of features and targets in the `aqo_data` view is a logarithm to base  $e$ , to get the actual value, raise  $e$  to this power. For example: `exp(0)`:

| fs                  | fss         | nfeatures | targets                                                                           | reliability |
|---------------------|-------------|-----------|-----------------------------------------------------------------------------------|-------------|
| features            |             |           |                                                                                   |             |
| oids                |             |           |                                                                                   |             |
| -727505571757520766 | 2128507884  | 4         | {-0.03438753143452488,-5.634789603169249,-0.3149847743198556,-8.006367567650246}} | {1}         |
| -727505571757520766 | -1076069505 | 0         | {2.302585092994046}                                                               | {1}         |
| -727505571757520766 | -1838231581 | 0         | {8.006367567650246}                                                               | {1}         |
| -727505571757520766 | -303037802  | 3         | {-0.03438753143452488,-5.634789603169249,-0.3149847743198556}}                    | {1}         |
| -727505571757520766 | -636613046  | 2         | {-0.03438753143452488,-0.3149847743198556}}                                       | {1}         |

(6 rows)

When the query is executed for the second time, aqo recognizes the query and makes a prediction. Pay attention to the cardinality predicted by aqo and the value of aqo error ("error=0%").

```

postgres=# EXPLAIN (ANALYZE, SUMMARY OFF, TIMING OFF) select count(*) from score join
course on score.cno=course.cno join student on score.sno=student.sno where degree<90
and test_preparation = 0;

```

In case of an error, values of features and targets must change, but as there was no error above, they did not change.

| fs                  | fss         | nfeatures           | targets                                                                           | reliability |

(6 rows)

Let's change a constant in the query, and you will notice that the prediction is made with an error:

```
postgres=# EXPLAIN (ANALYZE, SUMMARY OFF, TIMING OFF) select count(*) from score
join course on score.cno=course.cno join student on score.sno=student.sno where
degree<80 and test_preparation = 0;
```

## QUERY PLAN

```
Aggregate (cost=305.86..305.87 rows=1 width=8) (actual rows=1 loops=1)
  AJO not used, fss=0
-> Hash Join (cost=121.42..296.74 rows=3649 width=0) (actual rows=3551 loops=1)
    AJO: rows=3649, error=3%, fss=2128507884
    Hash Cond: (score.sno = student.sno)
```

## Additional Supplied Modules and Extensions Shipped in

postgrespro-ent-14-contrib

```

-> Hash Join (cost=12.93..178.65 rows=3649 width=4) (actual rows=3551
loops=1)
    AJO: rows=3649, error=3%, fss=-303037802
    Hash Cond: (score.cno = course.cno)
    -> Seq Scan on score (cost=0.00..156.00 rows=3649 width=8) (actual
rows=3551 loops=1)
        AJO: rows=3649, error=3%, fss=-636613046
        Filter: ((degree < 80) AND (test_preparation = 0))
        Rows Removed by Filter: 1449
    -> Hash (cost=12.80..12.80 rows=10 width=4) (actual rows=10 loops=1)
        Buckets: 1024 Batches: 1 Memory Usage: 9kB
        -> Seq Scan on course (cost=0.00..12.80 rows=10 width=4) (actual

### Example F.2. Using the [aqo\\_query\\_stat](#) View

The `aqo_query_stats` view shows statistics on the query planning time, query execution time and cardinality error. Based on this data you can make a decision whether to use aqp predictions for different query classes.

Let's query the `aqo_query_stats` view:

```
select queryid, cardinality_error_with_aqp,
cardinality_error_without_aqp, execution_time_with_aqp, execution_time_without_aqp,
planning_time_with_aqp, planning_time_without_aqp from aqp_query_stat \gx
-[ RECORD 1 ]-----
+-----
queryid          | 8041624334006338922
cardinality_error_with_aqp |
{0.14932737556062836,0,0.507421202801325,0.00040469447777891077}
cardinality_error_without_aqp | {0.1493979460962751,0.018403615483185476}
execution_time_with_aqp      | {0.004760108,0.008743075,0.006608304,0.012392751}
execution_time_without_aqp   | {0.005775926,0.012730316}
planning_time_with_aqp      | {0.006927997,0.004247339,0.005005022,0.004169717}
planning_time_without_aqp    | {0.001783542,0.001706121}
```

The retrieved data is for the query from [Example F.1](#), which was executed once without aqo for each of the parameters `degree<80` and `degree<90` and twice with aqo for each of these parameters. It is clear that with aqo, the cardinality error decreases to 0.0004, while the minimum cardinality error without aqo is 0.15. Besides, the execution time with aqo is lower than without it. So the conclusion is that aqo learns well on this query, and the prediction can be used for this query class.

## F.4.5. Author

Oleg Ivanov

## F.5. auth\_delay

`auth_delay` causes the server to pause briefly before reporting authentication failure, to make brute-force attacks on database passwords more difficult. Note that it does nothing to prevent denial-of-service attacks, and may even exacerbate them, since processes that are waiting before reporting authentication failure will still consume connection slots.

In order to function, this module must be loaded via [shared\\_preload\\_libraries](#) in `postgresql.conf`.

### F.5.1. Configuration Parameters

`auth_delay.milliseconds (int)`

The number of milliseconds to wait before reporting an authentication failure. The default is 0.

These parameters must be set in `postgresql.conf`. Typical usage might be:

```
# postgresql.conf
shared_preload_libraries = 'auth_delay'

auth_delay.milliseconds = '500'
```

## F.5.2. Author

KaiGai Kohei <kaigai@ak.jp.nec.com>

## F.6. auto\_dump

The `auto_dump` module is a Postgres Pro extension that is designed to collect data on long-running and problematic queries and to further reproduce these problems for troubleshooting.

To simplify reproducing problematic queries, this extension generates a dump file containing the following entities:

1. `CREATE TABLE` statements for both temporary and permanent tables referenced in the query.
2. `INSERT/COPY` statements to populate the tables with data available during the original problematic query execution.
3. The original problematic SQL query along with its execution plan, which can be generated by `EXPLAIN`, `EXPLAIN ANALYZE`, or both.

### F.6.1. Installation and Configuration

The `auto_dump` extension is included into Postgres Pro Enterprise. Once you have Postgres Pro Enterprise installed, complete the following steps to enable `auto_dump`:

1. Add `auto_dump` to the [shared\\_preload\\_libraries](#) parameter in the `postgresql.conf` file:

```
shared_preload_libraries = 'auto_dump'
```

2. As `auto_dump` is disabled by default, enable it:

```
auto_dump.enable = on
```

Before using the extension, set other [required configuration parameters](#) and restart the database server for the changes to take effect.

## F.6.2. Configuration Parameters

The `auto_dump` extension provides the following configuration parameters for managing automatic query dumping parameters.

### F.6.2.1. General Configuration Parameters

`auto_dump.enable` (boolean)

Enables the extension. This parameter is disabled by default.

`auto_dump.output_directory` (string)

Specifies the file system path to the directory where table dump files are saved. This is a mandatory parameter. The operating system user the service run as must have read-write permissions for this directory.

### F.6.2.2. Trigger Condition Control Parameters

The following configuration parameters control the conditions that trigger automatic query dumps.

`auto_dump.dump_on_query_string` (string)

Specifies a case-insensitive fragment of an SQL query. If this fragment appears anywhere in a query, the query is dumped. The default is an empty string ( ' ' ), which means that no query is dumped.

`auto_dump.dump_on_cancel` (boolean)

Controls whether a dump is triggered for queries that are canceled by the DBMS, for example, by the `pg_cancel_backend` function or due to a lock timeout.

Note that `auto_dump.dump_on_cancel` does not trigger dumps for sessions terminated due to [idle\\_in\\_transaction\\_session\\_timeout](#) or [idle\\_session\\_timeout](#).

This parameter is disabled by default.

`auto_dump.dump_on_bad_plan` (boolean)

Analyzes the expected and actual row counts for all queries. It uses two thresholds to identify problematic queries: [auto\\_dump.bad\\_plan\\_count\\_threshold](#) and [auto\\_dump.bad\\_plan\\_percent\\_threshold](#). An automatic dump is triggered for a query only when the difference in row counts exceeds both thresholds simultaneously.

This parameter is disabled by default.

`auto_dump.bad_plan_count_threshold` (integer)

Defines a trigger condition for automatic dumps based on the absolute difference between the expected and actual row counts.

All nodes of the execution plan are analyzed. The condition is considered satisfied if the difference between the expected and actual row counts exceeds this parameter value.

If the value is set to 0, the condition is always considered satisfied. The default value is 1000000.

`auto_dump.bad_plan_percent_threshold` (integer)

Defines a trigger condition for automatic dumps based on the percentage difference between the expected and actual row counts. The possible value is an integer between 0 and 100 (default).

All nodes of the execution plan are analyzed. For each node, the percentage difference between expected and actual row counts is checked. The condition is considered satisfied if this difference exceeds this parameter value.

If this value is set to 0, the condition is always considered satisfied.

`auto_dump.dump_on_time` (boolean)

Saves a dump for a query if its execution time exceeds the `auto_dump.timeout` value. This parameter is disabled by default.

`auto_dump.timeout` (integer)

Specifies the timeout value for `auto_dump.dump_on_time` in milliseconds. Possible values are integers greater than or equal to 0 (default). If the value is set to 0, every query is dumped.

If multiple trigger condition control parameters are specified, they are processed in the following order:

1. `auto_dump.dump_on_cancel`
2. `auto_dump.dump_on_query_string`
3. `auto_dump.dump_on_bad_plan`
4. `auto_dump.dump_on_time`

### F.6.2.3. Dump Content Control Parameters

The following configuration parameters control the scope and content of automatic dumps.

`auto_dump.dump_temporary_tables` (boolean)

Writes session temporary tables used by the current query to the dump. This parameter is disabled by default.

`auto_dump.dump_persistent_tables` (boolean)

Writes all persistent tables used by the current query to the dump. This parameter is disabled by default.

`auto_dump.dump_all_temp_tables` (boolean)

Writes all session temporary tables, including those used by the current query, to the dump. This parameter is disabled by default.

`auto_dump.dump_data` (boolean)

Writes the table content to the dump. When disabled, the SQL query only includes table creation commands without populating them with data. This parameter is disabled by default.

Enable this parameter together with `auto_dump.dump_temporary_tables` or `auto_dump.dump_persistent_tables` to create an SQL file with table contents.

`auto_dump.dump_indexes` (boolean)

Writes index creation commands for tables to the dump. This parameter is disabled by default.

`auto_dump.dump_copy_data` (boolean)

Specifies the method for dumping table data.

If enabled, dumps table data using the `COPY TO` command. As a result, a separate TXT file for each table is created, which is referenced by a `COPY ... FROM` statement in the dump file.

If disabled, dumps table data as `INSERT` statements in the dump file containing all table values.

This parameter is disabled by default.

`auto_dump.dump_query` (boolean)

Writes the SQL query for which the dump is created to the dump. This parameter is disabled by default.

`auto_dump.dump_create` (boolean)

Writes SQL commands for creating the tables being dumped to the dump. This parameter is disabled by default.

`auto_dump.dump_plan` (boolean)

Writes the execution plan of the current SQL query to the dump. This parameter is disabled by default.

### F.6.3. Limitations and Considerations

Use `auto_dump` with caution. This extension is designed as a debugging tool and cannot be used for continuous monitoring. Thus, it is not recommended to configure `auto_dump` to dump every query.

`auto_dump` operation can cause conflicts, particularly when dumping temporary tables or data. Consider the following possible issues:

- The `auto_dump` extension is incompatible with the `PREPARE TRANSACTION` command when working with temporary tables. A check for operations on temporary objects occurs earlier than the check for enabled prepared transactions, so an error occurs even if `max_prepared_transactions` is correctly configured.
- When `auto_dump.dump_all_temp_tables` is enabled, `auto_dump` cannot access temporary namespaces from autonomous transactions. A corresponding error message is raised in this case.
- The performance statistics can also be affected. When `auto_dump.dump_data` is enabled, the extension reads table data to generate dumps and thus artificially inflates the number of sequential scans, which leads to inaccurate statistics.

## F.7. auto\_explain

The `auto_explain` module provides a means for logging execution plans of slow statements automatically, without having to run `EXPLAIN` by hand. This is especially helpful for tracking down un-optimized queries in large applications.

The module provides no SQL-accessible functions. To use it, simply load it into the server. You can load it into an individual session:

```
LOAD 'auto_explain';
```

(You must be superuser to do that.) More typical usage is to preload it into some or all sessions by including `auto_explain` in `session_preload_libraries` or `shared_preload_libraries` in `postgresql.conf`. Then you can track unexpectedly slow queries no matter when they happen. Of course there is a price in overhead for that.

### F.7.1. Configuration Parameters

There are several configuration parameters that control the behavior of `auto_explain`. Note that the default behavior is to do nothing, so you must set at least `auto_explain.log_min_duration` if you want any results.

`auto_explain.log_min_duration` (integer)

`auto_explain.log_min_duration` is the minimum statement execution time, in milliseconds, that will cause the statement's plan to be logged. Setting this to 0 logs all plans. -1 (the default) disables logging of plans. For example, if you set it to 250ms then all statements that run 250ms or longer will be logged. Only superusers can change this setting.

`auto_explain.log_analyze` (boolean)

`auto_explain.log_analyze` causes `EXPLAIN ANALYZE` output, rather than just `EXPLAIN` output, to be printed when an execution plan is logged. This parameter is off by default. Only superusers can change this setting.

## Note

When this parameter is on, per-plan-node timing occurs for all statements executed, whether or not they run long enough to actually get logged. This can have an extremely negative impact on performance. Turning off `auto_explain.log_timing` ameliorates the performance cost, at the price of obtaining less information.

`auto_explain.log_buffers` (boolean)

`auto_explain.log_buffers` controls whether buffer usage statistics are printed when an execution plan is logged; it's equivalent to the `BUFFERS` option of `EXPLAIN`. This parameter has no effect unless `auto_explain.log_analyze` is enabled. This parameter is off by default. Only superusers can change this setting.

`auto_explain.log_wal` (boolean)

`auto_explain.log_wal` controls whether WAL usage statistics are printed when an execution plan is logged; it's equivalent to the `WAL` option of `EXPLAIN`. This parameter has no effect unless `auto_explain.log_analyze` is enabled. This parameter is off by default. Only superusers can change this setting.

`auto_explain.log_timing` (boolean)

`auto_explain.log_timing` controls whether per-node timing information is printed when an execution plan is logged; it's equivalent to the `TIMING` option of `EXPLAIN`. The overhead of repeatedly reading the system clock can slow down queries significantly on some systems, so it may be useful to set this parameter to off when only actual row counts, and not exact times, are needed. This parameter has no effect unless `auto_explain.log_analyze` is enabled. This parameter is on by default. Only superusers can change this setting.

`auto_explain.log_triggers` (boolean)

`auto_explain.log_triggers` causes trigger execution statistics to be included when an execution plan is logged. This parameter has no effect unless `auto_explain.log_analyze` is enabled. This parameter is off by default. Only superusers can change this setting.

`auto_explain.log_verbose` (boolean)

`auto_explain.log_verbose` controls whether verbose details are printed when an execution plan is logged; it's equivalent to the `VERBOSE` option of `EXPLAIN`. This parameter is off by default. Only superusers can change this setting.

`auto_explain.log_settings` (boolean)

`auto_explain.log_settings` controls whether information about modified configuration options is printed when an execution plan is logged. Only options affecting query planning with value different from the built-in default value are included in the output. This parameter is off by default. Only superusers can change this setting.

`auto_explain.log_format` (enum)

`auto_explain.log_format` selects the `EXPLAIN` output format to be used. The allowed values are `text`, `xml`, `json`, and `yaml`. The default is `text`. Only superusers can change this setting.

`auto_explain.log_level` (enum)

`auto_explain.log_level` selects the log level at which `auto_explain` will log the query plan. Valid values are `DEBUG5`, `DEBUG4`, `DEBUG3`, `DEBUG2`, `DEBUG1`, `INFO`, `NOTICE`, `WARNING`, and `LOG`. The default is `LOG`. Only superusers can change this setting.

`auto_explain.log_nested_statements` (boolean)

`auto_explain.log_nested_statements` causes nested statements (statements executed inside a function) to be considered for logging. When it is off, only top-level query plans are logged. This parameter is off by default. Only superusers can change this setting.

`auto_explain.sample_rate` (real)

`auto_explain.sample_rate` causes `auto_explain` to only explain a fraction of the statements in each session. The default is 1, meaning explain all the queries. In case of nested statements, either all will be explained or none. Only superusers can change this setting.

In ordinary usage, these parameters are set in `postgresql.conf`, although superusers can alter them on-the-fly within their own sessions. Typical usage might be:

```
# postgresql.conf
session_preload_libraries = 'auto_explain'

auto_explain.log_min_duration = '3s'
```

## F.7.2. Example

```
postgres=# LOAD 'auto_explain';
postgres=# SET auto_explain.log_min_duration = 0;
postgres=# SET auto_explain.log_analyze = true;
postgres=# SELECT count(*)
           FROM pg_class, pg_index
           WHERE oid = indrelid AND indisunique;
```

This might produce log output such as:

```
LOG:  duration: 0.196 ms plan:
       Query Text: SELECT count(*)
                   FROM pg_class, pg_index
                   WHERE oid = indrelid AND indisunique;
       Aggregate  (cost=16.79..16.80 rows=1 width=0) (actual time=3.626..3.627 rows=1
loops=1)
       -> Hash Join  (cost=4.17..16.55 rows=92 width=0) (actual time=3.349..3.594 rows=92
loops=1)
           Hash Cond: (pg_class.oid = pg_index.indrelid)
           -> Seq Scan on pg_class  (cost=0.00..9.55 rows=255 width=4) (actual
time=0.016..0.140 rows=255 loops=1)
           -> Hash  (cost=3.02..3.02 rows=92 width=4) (actual time=3.238..3.238 rows=92
loops=1)
               Buckets: 1024  Batches: 1  Memory Usage: 4kB
               -> Seq Scan on pg_index  (cost=0.00..3.02 rows=92 width=4) (actual
time=0.008..3.187 rows=92 loops=1)
                   Filter: indisunique
       Planning Time: 0.548 ms
```

Note that Postgres Pro added a new field to the output to show planning time.

## F.7.3. Authors

Postgres Professional, Moscow, Russia

## F.8. bloom

`bloom` provides an index access method based on *Bloom filters*.

A Bloom filter is a space-efficient data structure that is used to test whether an element is a member of a set. In the case of an index access method, it allows fast exclusion of non-matching tuples via signatures whose size is determined at index creation.

A signature is a lossy representation of the indexed attribute(s), and as such is prone to reporting false positives; that is, it may be reported that an element is in the set, when it is not. So index search results must always be rechecked using the actual attribute values from the heap entry. Larger signatures reduce the odds of a false positive and thus reduce the number of useless heap visits, but of course also make the index larger and hence slower to scan.

This type of index is most useful when a table has many attributes and queries test arbitrary combinations of them. A traditional btree index is faster than a bloom index, but it can require many btree indexes to support all possible queries where one needs only a single bloom index. Note however that bloom indexes only support equality queries, whereas btree indexes can also perform inequality and range searches.

## F.8.1. Parameters

A bloom index accepts the following parameters in its `WITH` clause:

`length`

Length of each signature (index entry) in bits. It is rounded up to the nearest multiple of 16. The default is 80 bits and the maximum is 4096.

`col1 – col32`

Number of bits generated for each index column. Each parameter's name refers to the number of the index column that it controls. The default is 2 bits and the maximum is 4095. Parameters for index columns not actually used are ignored.

## F.8.2. Examples

This is an example of creating a bloom index:

```
CREATE INDEX bloomidx ON tbloom USING bloom (i1,i2,i3)
WITH (length=80, col1=2, col2=2, col3=4);
```

The index is created with a signature length of 80 bits, with attributes `i1` and `i2` mapped to 2 bits, and attribute `i3` mapped to 4 bits. We could have omitted the `length`, `col1`, and `col2` specifications since those have the default values.

Here is a more complete example of bloom index definition and usage, as well as a comparison with equivalent btree indexes. The bloom index is considerably smaller than the btree index, and can perform better.

```
=# CREATE TABLE tbloom AS
SELECT
  (random() * 1000000)::int as i1,
  (random() * 1000000)::int as i2,
  (random() * 1000000)::int as i3,
  (random() * 1000000)::int as i4,
  (random() * 1000000)::int as i5,
  (random() * 1000000)::int as i6
FROM
  generate_series(1,10000000);
SELECT 10000000
```

A sequential scan over this large table takes a long time:

```
=# EXPLAIN ANALYZE SELECT * FROM tbloom WHERE i2 = 898732 AND i5 = 123451;
QUERY PLAN
```

```
-----
-----
```

**Additional Supplied Modules  
and Extensions Shipped in  
postgrespro-ent-14-contrib**

---

```
Seq Scan on tbloom  (cost=0.00..213744.00 rows=250 width=24) (actual
time=357.059..357.059 rows=0 loops=1)
  Filter: ((i2 = 898732) AND (i5 = 123451))
  Rows Removed by Filter: 10000000
Planning Time: 0.346 ms
Execution Time: 357.076 ms
(5 rows)
```

Even with the btree index defined the result will still be a sequential scan:

```
=# CREATE INDEX btreeidx ON tbloom (i1, i2, i3, i4, i5, i6);
CREATE INDEX
=# SELECT pg_size_pretty(pg_relation_size('btreeidx'));
pg_size_pretty
-----
386 MB
(1 row)
=# EXPLAIN ANALYZE SELECT * FROM tbloom WHERE i2 = 898732 AND i5 = 123451;
                                QUERY PLAN
-----
Seq Scan on tbloom  (cost=0.00..213744.00 rows=2 width=24) (actual
time=351.016..351.017 rows=0 loops=1)
  Filter: ((i2 = 898732) AND (i5 = 123451))
  Rows Removed by Filter: 10000000
Planning Time: 0.138 ms
Execution Time: 351.035 ms
(5 rows)
```

Having the bloom index defined on the table is better than btree in handling this type of search:

```
=# CREATE INDEX bloomidx ON tbloom USING bloom (i1, i2, i3, i4, i5, i6);
CREATE INDEX
=# SELECT pg_size_pretty(pg_relation_size('bloomidx'));
pg_size_pretty
-----
153 MB
(1 row)
=# EXPLAIN ANALYZE SELECT * FROM tbloom WHERE i2 = 898732 AND i5 = 123451;
                                QUERY PLAN
-----
Bitmap Heap Scan on tbloom  (cost=1792.00..1799.69 rows=2 width=24) (actual
time=22.605..22.606 rows=0 loops=1)
  Recheck Cond: ((i2 = 898732) AND (i5 = 123451))
  Rows Removed by Index Recheck: 2300
  Heap Blocks: exact=2256
-> Bitmap Index Scan on bloomidx  (cost=0.00..178436.00 rows=1 width=0) (actual
time=20.005..20.005 rows=2300 loops=1)
  Index Cond: ((i2 = 898732) AND (i5 = 123451))
Planning Time: 0.099 ms
Execution Time: 22.632 ms
(8 rows)
```

Now, the main problem with the btree search is that btree is inefficient when the search conditions do not constrain the leading index column(s). A better strategy for btree is to create a separate index on each column. Then the planner will choose something like this:

```
=# CREATE INDEX btreeidx1 ON tbloom (i1);
CREATE INDEX
```

```
=# CREATE INDEX btreeidx2 ON tbloom (i2);
CREATE INDEX
=# CREATE INDEX btreeidx3 ON tbloom (i3);
CREATE INDEX
=# CREATE INDEX btreeidx4 ON tbloom (i4);
CREATE INDEX
=# CREATE INDEX btreeidx5 ON tbloom (i5);
CREATE INDEX
=# CREATE INDEX btreeidx6 ON tbloom (i6);
CREATE INDEX
=# EXPLAIN ANALYZE SELECT * FROM tbloom WHERE i2 = 898732 AND i5 = 123451;
                                QUERY PLAN
-----
Bitmap Heap Scan on tbloom  (cost=9.29..13.30 rows=1 width=24) (actual
time=0.032..0.033 rows=0 loops=1)
    Recheck Cond: ((i5 = 123451) AND (i2 = 898732))
    -> BitmapAnd  (cost=9.29..9.29 rows=1 width=0) (actual time=0.047..0.047 rows=0
loops=1)
        -> Bitmap Index Scan on btreeidx5  (cost=0.00..4.52 rows=11 width=0) (actual
time=0.026..0.026 rows=7 loops=1)
            Index Cond: (i5 = 123451)
        -> Bitmap Index Scan on btreeidx2  (cost=0.00..4.52 rows=11 width=0) (actual
time=0.007..0.007 rows=8 loops=1)
            Index Cond: (i2 = 898732)
Planning Time: 0.264 ms
Execution Time: 0.047 ms
(9 rows)
```

Although this query runs much faster than with either of the single indexes, we pay a penalty in index size. Each of the single-column btree indexes occupies 88.5 MB, so the total space needed is 531 MB, over three times the space used by the bloom index.

### F.8.3. Operator Class Interface

An operator class for bloom indexes requires only a hash function for the indexed data type and an equality operator for searching. This example shows the operator class definition for the `text` data type:

```
CREATE OPERATOR CLASS text_ops
DEFAULT FOR TYPE text USING bloom AS
    OPERATOR      1      =(text, text),
    FUNCTION      1      hashtext(text);
```

### F.8.4. Limitations

- Only operator classes for `int4` and `text` are included with the module.
- Only the `=` operator is supported for search. But it is possible to add support for arrays with union and intersection operations in the future.
- `bloom` access method doesn't support `UNIQUE` indexes.
- `bloom` access method doesn't support searching for `NULL` values.

### F.8.5. Authors

Teodor Sigaev <teodor@postgrespro.ru>, Postgres Professional, Moscow, Russia

## F.9. btree\_gin

`btree_gin` provides sample GIN operator classes that implement B-tree equivalent behavior for the data types `int2`, `int4`, `int8`, `float4`, `float8`, `timestamp with time zone`, `timestamp without time zone`, `time with time zone`, `time without time zone`, `date`, `interval`, `oid`, `money`, `"char"`, `varchar`, `text`, `bytea`, `bit`, `varbit`, `macaddr`, `macaddr8`, `inet`, `cidr`, `uuid`, `name`, `bool`, `bpchar`, and all enum types.

In general, these operator classes will not outperform the equivalent standard B-tree index methods, and they lack one major feature of the standard B-tree code: the ability to enforce uniqueness. However, they are useful for GIN testing and as a base for developing other GIN operator classes. Also, for queries that test both a GIN-indexable column and a B-tree-indexable column, it might be more efficient to create a multicolumn GIN index that uses one of these operator classes than to create two separate indexes that would have to be combined via bitmap ANDing.

This module is considered “trusted”, that is, it can be installed by non-superusers who have `CREATE` privilege on the current database.

### F.9.1. Example Usage

```
CREATE TABLE test (a int4);
-- create index
CREATE INDEX testidx ON test USING GIN (a);
-- query
SELECT * FROM test WHERE a < 10;
```

### F.9.2. Authors

Teodor Sigaev (<teodor@stack.net>) and Oleg Bartunov (<oleg@sai.msu.su>). See <http://www.sai.msu.su/~megera/oddmuse/index.cgi/Gin> for additional information.

## F.10. btree\_gist

`btree_gist` provides GiST index operator classes that implement B-tree equivalent behavior for the data types `int2`, `int4`, `int8`, `float4`, `float8`, `numeric`, `timestamp with time zone`, `timestamp without time zone`, `time with time zone`, `time without time zone`, `date`, `interval`, `oid`, `money`, `char`, `varchar`, `text`, `bytea`, `bit`, `varbit`, `macaddr`, `macaddr8`, `inet`, `cidr`, `uuid`, and all enum types.

In general, these operator classes will not outperform the equivalent standard B-tree index methods, and they lack one major feature of the standard B-tree code: the ability to enforce uniqueness. However, they provide some other features that are not available with a B-tree index, as described below. Also, these operator classes are useful when a multicolumn GiST index is needed, wherein some of the columns are of data types that are only indexable with GiST but other columns are just simple data types. Lastly, these operator classes are useful for GiST testing and as a base for developing other GiST operator classes.

In addition to the typical B-tree search operators, `btree_gist` also provides index support for `<>` (“not equals”). This may be useful in combination with an [exclusion constraint](#), as described below.

Also, for data types for which there is a natural distance metric, `btree_gist` defines a distance operator `<->`, and provides GiST index support for nearest-neighbor searches using this operator. Distance operators are provided for `int2`, `int4`, `int8`, `float4`, `float8`, `timestamp with time zone`, `timestamp without time zone`, `time without time zone`, `date`, `interval`, `oid`, and `money`.

This module is considered “trusted”, that is, it can be installed by non-superusers who have `CREATE` privilege on the current database.

### F.10.1. Example Usage

Simple example using `btree_gist` instead of `btree`:

```
CREATE TABLE test (a int4);
-- create index
```

```
CREATE INDEX testidx ON test USING GIST (a);
-- query
SELECT * FROM test WHERE a < 10;
-- nearest-neighbor search: find the ten entries closest to "42"
SELECT *, a <-> 42 AS dist FROM test ORDER BY a <-> 42 LIMIT 10;
```

Use an [exclusion constraint](#) to enforce the rule that a cage at a zoo can contain only one kind of animal:

```
=> CREATE TABLE zoo (
    cage    INTEGER,
    animal  TEXT,
    EXCLUDE USING GIST (cage WITH =, animal WITH <>)
);

=> INSERT INTO zoo VALUES(123, 'zebra');
INSERT 0 1
=> INSERT INTO zoo VALUES(123, 'zebra');
INSERT 0 1
=> INSERT INTO zoo VALUES(123, 'lion');
ERROR:  conflicting key value violates exclusion constraint "zoo_cage_animal_excl"
DETAIL:  Key (cage, animal)=(123, lion) conflicts with existing key (cage,
        animal)=(123, zebra).
=> INSERT INTO zoo VALUES(124, 'lion');
INSERT 0 1
```

## F.10.2. Upgrade notes for version 1.6

In version 1.6 `btree_gist` switched to using in-core distance operators, and its own implementations were removed. References to these operators in `btree_gist` opclasses will be updated automatically during the extension upgrade, but if the user has created objects referencing these operators or functions, then these objects must be dropped manually before updating the extension.

## F.10.3. Authors

Teodor Sigaev (<teodor@stack.net>), Oleg Bartunov (<oleg@sai.msu.su>), Janko Richter (<janko-richter@yahoo.de>), and Paul Jungwirth (<pj@illuminatedcomputing.com>). See <http://www.sai.msu.su/~megeera/postgres/gist/> for additional information.

## F.11. citext

The `citext` module provides a case-insensitive character string type, `citext`. Essentially, it internally calls `lower` when comparing values. Otherwise, it behaves almost exactly like `text`.

### Tip

Consider using *nondeterministic collations* (see [Section 23.2.2.4](#)) instead of this module. They can be used for case-insensitive comparisons, accent-insensitive comparisons, and other combinations, and they handle more Unicode special cases correctly.

This module is considered “trusted”, that is, it can be installed by non-superusers who have `CREATE` privilege on the current database.

### F.11.1. Rationale

The standard approach to doing case-insensitive matches in Postgres Pro has been to use the `lower` function when comparing values, for example

```
SELECT * FROM tab WHERE lower(col) = LOWER(?);
```

This works reasonably well, but has a number of drawbacks:

- It makes your SQL statements verbose, and you always have to remember to use `lower` on both the column and the query value.
- It won't use an index, unless you create a functional index using `lower`.
- If you declare a column as `UNIQUE` or `PRIMARY KEY`, the implicitly generated index is case-sensitive. So it's useless for case-insensitive searches, and it won't enforce uniqueness case-insensitively.

The `citext` data type allows you to eliminate calls to `lower` in SQL queries, and allows a primary key to be case-insensitive. `citext` is locale-aware, just like `text`, which means that the matching of upper case and lower case characters is dependent on the rules of the database's `LC_CTYPE` setting. Again, this behavior is identical to the use of `lower` in queries. But because it's done transparently by the data type, you don't have to remember to do anything special in your queries.

### F.11.2. How to Use It

Here's a simple example of usage:

```
CREATE TABLE users (  
    nick CITEXT PRIMARY KEY,  
    pass TEXT    NOT NULL  
);  
  
INSERT INTO users VALUES ( 'larry',  sha256(random()::text::bytea) );  
INSERT INTO users VALUES ( 'Tom',    sha256(random()::text::bytea) );  
INSERT INTO users VALUES ( 'Damian', sha256(random()::text::bytea) );  
INSERT INTO users VALUES ( 'NEAL',   sha256(random()::text::bytea) );  
INSERT INTO users VALUES ( 'Bjørn',  sha256(random()::text::bytea) );  
  
SELECT * FROM users WHERE nick = 'Larry';
```

The `SELECT` statement will return one tuple, even though the `nick` column was set to `larry` and the query was for `Larry`.

### F.11.3. String Comparison Behavior

`citext` performs comparisons by converting each string to lower case (as though `lower` were called) and then comparing the results normally. Thus, for example, two strings are considered equal if `lower` would produce identical results for them.

In order to emulate a case-insensitive collation as closely as possible, there are `citext`-specific versions of a number of string-processing operators and functions. So, for example, the regular expression operators `~` and `~*` exhibit the same behavior when applied to `citext`: they both match case-insensitively. The same is true for `!~` and `!~*`, as well as for the `LIKE` operators `~~` and `~~*`, and `!~~` and `!~~*`. If you'd like to match case-sensitively, you can cast the operator's arguments to `text`.

Similarly, all of the following functions perform matching case-insensitively if their arguments are `citext`:

- `regexp_match()`
- `regexp_matches()`
- `regexp_replace()`
- `regexp_split_to_array()`
- `regexp_split_to_table()`
- `replace()`
- `split_part()`
- `strpos()`
- `translate()`

For the regexp functions, if you want to match case-sensitively, you can specify the “c” flag to force a case-sensitive match. Otherwise, you must cast to `text` before using one of these functions if you want case-sensitive behavior.

## F.11.4. Limitations

- `citext`'s case-folding behavior depends on the `LC_CTYPE` setting of your database. How it compares values is therefore determined when the database is created. It is not truly case-insensitive in the terms defined by the Unicode standard. Effectively, what this means is that, as long as you're happy with your collation, you should be happy with `citext`'s comparisons. But if you have data in different languages stored in your database, users of one language may find their query results are not as expected if the collation is for another language.
- As of PostgreSQL 9.1, you can attach a `COLLATE` specification to `citext` columns or data values. Currently, `citext` operators will honor a non-default `COLLATE` specification while comparing case-folded strings, but the initial folding to lower case is always done according to the database's `LC_CTYPE` setting (that is, as though `COLLATE "default"` were given). This may be changed in a future release so that both steps follow the input `COLLATE` specification.
- `citext` is not as efficient as `text` because the operator functions and the B-tree comparison functions must make copies of the data and convert it to lower case for comparisons. Also, only `text` can support B-Tree deduplication. However, `citext` is slightly more efficient than using `lower` to get case-insensitive matching.
- `citext` doesn't help much if you need data to compare case-sensitively in some contexts and case-insensitively in other contexts. The standard answer is to use the `text` type and manually use the `lower` function when you need to compare case-insensitively; this works all right if case-insensitive comparison is needed only infrequently. If you need case-insensitive behavior most of the time and case-sensitive infrequently, consider storing the data as `citext` and explicitly casting the column to `text` when you want case-sensitive comparison. In either situation, you will need two indexes if you want both types of searches to be fast.
- The schema containing the `citext` operators must be in the current `search_path` (typically `public`); if it is not, the normal case-sensitive `text` operators will be invoked instead.
- The approach of lower-casing strings for comparison does not handle some Unicode special cases correctly, for example when one upper-case letter has two lower-case letter equivalents. Unicode distinguishes between *case mapping* and *case folding* for this reason. Use nondeterministic collations instead of `citext` to handle that correctly.

## F.11.5. Author

David E. Wheeler <david@kineticcode.com>

Inspired by the original `citext` module by Donald Fraser.

## F.12. cube

This module implements a data type `cube` for representing multidimensional cubes.

This module is considered “trusted”, that is, it can be installed by non-superusers who have `CREATE` privilege on the current database.

### F.12.1. Syntax

Table F.12 shows the valid external representations for the `cube` type.  $x$ ,  $y$ , etc. denote floating-point numbers.

Table F.12. Cube External Representations

| External Syntax | Meaning                                                            |
|-----------------|--------------------------------------------------------------------|
| $x$             | A one-dimensional point (or, zero-length one-dimensional interval) |

| External Syntax                                   | Meaning                                                                                                         |
|---------------------------------------------------|-----------------------------------------------------------------------------------------------------------------|
| <code>( x )</code>                                | Same as above                                                                                                   |
| <code>x1, x2, ..., xn</code>                      | A point in n-dimensional space, represented internally as a zero-volume cube                                    |
| <code>( x1, x2, ..., xn )</code>                  | Same as above                                                                                                   |
| <code>( x ), ( y )</code>                         | A one-dimensional interval starting at <i>x</i> and ending at <i>y</i> or vice versa; the order does not matter |
| <code>[ ( x ), ( y ) ]</code>                     | Same as above                                                                                                   |
| <code>( x1, ..., xn ), ( y1, ..., yn )</code>     | An n-dimensional cube represented by a pair of its diagonally opposite corners                                  |
| <code>[ ( x1, ..., xn ), ( y1, ..., yn ) ]</code> | Same as above                                                                                                   |

It does not matter which order the opposite corners of a cube are entered in. The `cube` functions automatically swap values if needed to create a uniform “lower left — upper right” internal representation. When the corners coincide, `cube` stores only one corner along with an “is point” flag to avoid wasting space.

White space is ignored on input, so `[ (x), (y) ]` is the same as `[ ( x ), ( y ) ]`.

## F.12.2. Precision

Values are stored internally as 64-bit floating point numbers. This means that numbers with more than about 16 significant digits will be truncated.

## F.12.3. Usage

Table F.13 shows the specialized operators provided for type `cube`.

**Table F.13. Cube Operators**

| Operator                                    | Description                                                                                                                                                                                                                                                                                                                                  |
|---------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>cube &amp;&amp; cube → boolean</code> | Do the cubes overlap?                                                                                                                                                                                                                                                                                                                        |
| <code>cube @&gt; cube → boolean</code>      | Does the first cube contain the second?                                                                                                                                                                                                                                                                                                      |
| <code>cube &lt;@ cube → boolean</code>      | Is the first cube contained in the second?                                                                                                                                                                                                                                                                                                   |
| <code>cube -&gt; integer → float8</code>    | Extracts the <i>n</i> -th coordinate of the cube (counting from 1).                                                                                                                                                                                                                                                                          |
| <code>cube ~&gt; integer → float8</code>    | Extracts the <i>n</i> -th coordinate of the cube, counting in the following way: $n = 2 * k - 1$ means lower bound of <i>k</i> -th dimension, $n = 2 * k$ means upper bound of <i>k</i> -th dimension. Negative <i>n</i> denotes the inverse value of the corresponding positive coordinate. This operator is designed for KNN-GiST support. |
| <code>cube &lt;-&gt; cube → float8</code>   | Computes the Euclidean distance between the two cubes.                                                                                                                                                                                                                                                                                       |
| <code>cube &lt;#&gt; cube → float8</code>   | Computes the taxicab (L-1 metric) distance between the two cubes.                                                                                                                                                                                                                                                                            |
| <code>cube &lt;=&gt; cube → float8</code>   | Computes the Chebyshev (L-inf metric) distance between the two cubes.                                                                                                                                                                                                                                                                        |

In addition to the above operators, the usual comparison operators shown in [Table 9.1](#) are available for type `cube`. These operators first compare the first coordinates, and if those are equal, compare the second coordinates, etc. They exist mainly to support the b-tree index operator class for `cube`, which can be useful for example if you would like a `UNIQUE` constraint on a `cube` column. Otherwise, this ordering is not of much practical use.

The `cube` module also provides a GiST index operator class for `cube` values. A `cube` GiST index can be used to search for values using the `=`, `&&`, `@>`, and `<@` operators in `WHERE` clauses.

In addition, a `cube` GiST index can be used to find nearest neighbors using the metric operators `<->`, `<#>`, and `<=>` in `ORDER BY` clauses. For example, the nearest neighbor of the 3-D point (0.5, 0.5, 0.5) could be found efficiently with:

```
SELECT c FROM test ORDER BY c <-> cube(array[0.5,0.5,0.5]) LIMIT 1;
```

The `~>` operator can also be used in this way to efficiently retrieve the first few values sorted by a selected coordinate. For example, to get the first few cubes ordered by the first coordinate (lower left corner) ascending one could use the following query:

```
SELECT c FROM test ORDER BY c ~> 1 LIMIT 5;
```

And to get 2-D cubes ordered by the first coordinate of the upper right corner descending:

```
SELECT c FROM test ORDER BY c ~> 3 DESC LIMIT 5;
```

[Table F.14](#) shows the available functions.

**Table F.14. Cube Functions**

| Function                                          | Description                                                                                                                                                                                            | Example(s)                                                            |
|---------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------|
| <code>cube ( float8 ) → cube</code>               | Makes a one dimensional cube with both coordinates the same.                                                                                                                                           | <code>cube(1) → (1)</code>                                            |
| <code>cube ( float8, float8 ) → cube</code>       | Makes a one dimensional cube.                                                                                                                                                                          | <code>cube(1, 2) → (1), (2)</code>                                    |
| <code>cube ( float8[] ) → cube</code>             | Makes a zero-volume cube using the coordinates defined by the array.                                                                                                                                   | <code>cube(ARRAY[1,2,3]) → (1, 2, 3)</code>                           |
| <code>cube ( float8[], float8[] ) → cube</code>   | Makes a cube with upper right and lower left coordinates as defined by the two arrays, which must be of the same length.                                                                               | <code>cube(ARRAY[1,2], ARRAY[3,4]) → (1, 2), (3, 4)</code>            |
| <code>cube ( cube, float8 ) → cube</code>         | Makes a new cube by adding a dimension on to an existing cube, with the same values for both endpoints of the new coordinate. This is useful for building cubes piece by piece from calculated values. | <code>cube('(1,2), (3,4) '::cube, 5) → (1, 2, 5), (3, 4, 5)</code>    |
| <code>cube ( cube, float8, float8 ) → cube</code> | Makes a new cube by adding a dimension on to an existing cube. This is useful for building cubes piece by piece from calculated values.                                                                | <code>cube('(1,2), (3,4) '::cube, 5, 6) → (1, 2, 5), (3, 4, 6)</code> |
| <code>cube_dim ( cube ) → integer</code>          |                                                                                                                                                                                                        |                                                                       |

| Function                                                         | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                | Example(s)                                                                                                                                                                     |

|                                                                  | Returns the number of dimensions of the cube.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              | <code>cube_dim(' (1,2), (3,4) ')</code> → 2                                                                                                                                    |
| <code>cube_ll_coord ( cube, integer ) → float8</code>            | Returns the <i>n</i> -th coordinate value for the lower left corner of the cube.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           | <code>cube_ll_coord(' (1,2), (3,4) ', 2)</code> → 2                                                                                                                            |
| <code>cube_ur_coord ( cube, integer ) → float8</code>            | Returns the <i>n</i> -th coordinate value for the upper right corner of the cube.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          | <code>cube_ur_coord(' (1,2), (3,4) ', 2)</code> → 4                                                                                                                            |
| <code>cube_is_point ( cube ) → boolean</code>                    | Returns true if the cube is a point, that is, the two defining corners are the same.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | <code>cube_is_point(cube(1,1))</code> → t                                                                                                                                      |
| <code>cube_distance ( cube, cube ) → float8</code>               | Returns the distance between two cubes. If both cubes are points, this is the normal distance function.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    | <code>cube_distance(' (1,2) ', ' (3,4) ')</code> → 2.8284271247461903                                                                                                          |
| <code>cube_subset ( cube, integer[] ) → cube</code>              | Makes a new cube from an existing cube, using a list of dimension indexes from an array. Can be used to extract the endpoints of a single dimension, or to drop dimensions, or to reorder them as desired.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 | <code>cube_subset(cube(' (1,3,5), (6,7,8) '), ARRAY[2])</code> → (3), (7)<br><code>cube_subset(cube(' (1,3,5), (6,7,8) '), ARRAY[3,2,1,1])</code> → (5, 3, 1, 1), (8, 7, 6, 6) |
| <code>cube_union ( cube, cube ) → cube</code>                    | Produces the union of two cubes.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           | <code>cube_union(' (1,2) ', ' (3,4) ')</code> → (1, 2), (3, 4)                                                                                                                 |
| <code>cube_inter ( cube, cube ) → cube</code>                    | Produces the intersection of two cubes.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    | <code>cube_inter(' (1,2) ', ' (3,4) ')</code> → (3, 4), (1, 2)                                                                                                                 |
| <code>cube_enlarge ( c cube, r double, n integer ) → cube</code> | Increases the size of the cube by the specified radius <i>r</i> in at least <i>n</i> dimensions. If the radius is negative the cube is shrunk instead. All defined dimensions are changed by the radius <i>r</i> . Lower-left coordinates are decreased by <i>r</i> and upper-right coordinates are increased by <i>r</i> . If a lower-left coordinate is increased to more than the corresponding upper-right coordinate (this can only happen when <i>r</i> < 0) then both coordinates are set to their average. If <i>n</i> is greater than the number of defined dimensions and the cube is being enlarged ( <i>r</i> > 0), then extra dimensions are added to make <i>n</i> altogether; 0 is used as the initial value for the extra coordinates. This function is useful for creating bounding boxes around a point for searching for nearby points. | <code>cube_enlarge(' (1,2), (3,4) ', 0.5, 3)</code> → (0.5, 1.5, -0.5), (3.5, 4.5, 0.5)                                                                                        |

## F.12.4. Defaults

I believe this union:

```
select cube_union(' (0,5,2), (2,3,1) ', '0');
cube_union
```

```
-----  
(0, 0, 0), (2, 5, 2)  
(1 row)
```

does not contradict common sense, neither does the intersection

```
select cube_inter('(0,-1), (1,1)', '(-2), (2)');  
cube_inter  
-----  
(0, 0), (1, 0)  
(1 row)
```

In all binary operations on differently-dimensioned cubes, I assume the lower-dimensional one to be a Cartesian projection, i. e., having zeroes in place of coordinates omitted in the string representation. The above examples are equivalent to:

```
cube_union('(0,5,2), (2,3,1)', '(0,0,0), (0,0,0)');  
cube_inter('(0,-1), (1,1)', '(-2,0), (2,0)');
```

The following containment predicate uses the point syntax, while in fact the second argument is internally represented by a box. This syntax makes it unnecessary to define a separate point type and functions for (box,point) predicates.

```
select cube_contains('(0,0), (1,1)', '0.5,0.5');  
cube_contains  
-----  
t  
(1 row)
```

## F.12.5. Notes

For examples of usage, see the regression test `sql/cube.sql`.

To make it harder for people to break things, there is a limit of 100 on the number of dimensions of cubes. This is set in `cubedata.h` if you need something bigger.

## F.12.6. Credits

Original author: Gene Selkov, Jr. <selkovjr@mcs.anl.gov>, Mathematics and Computer Science Division, Argonne National Laboratory.

My thanks are primarily to Prof. Joe Hellerstein (<https://dsf.berkeley.edu/jmh/>) for elucidating the gist of the GiST (<http://gist.cs.berkeley.edu/>), and to his former student Andy Dong for his example written for Illustra. I am also grateful to all Postgres developers, present and past, for enabling myself to create my own world and live undisturbed in it. And I would like to acknowledge my gratitude to Argonne Lab and to the U.S. Department of Energy for the years of faithful support of my database research.

Minor updates to this package were made by Bruno Wolff III <bruno@wolff.to> in August/September of 2002. These include changing the precision from single precision to double precision and adding some new functions.

Additional updates were made by Joshua Reich <josh@root.net> in July 2006. These include `cube(float8[], float8[])` and cleaning up the code to use the V1 call protocol instead of the deprecated V0 protocol.

## F.13. daterange\_inclusive

`daterange_inclusive` is an extension to the built-in `daterange` range type. By default, `daterange` excludes the upper bound of the range — `[]`, whereas `daterange_inclusive` does not — `[]`. Other than the covered range bound, there are no other differences between `daterange` and `daterange_inclusive`.

This module is considered “trusted”, that is, it can be installed by non-superusers who have `CREATE` privilege on the current database.

### F.13.1. Rationale

At times, it is more convenient to output date ranges with inclusive upper bounds. For example, it may apply to employees' absences. If an employee is absent from January 1, 2025, to January 10, 2025, using the `daterange` range type will prevent the database from outputting this date range in its entirety. In such cases, you would need to manually subtract one day from the output. The `daterange_inclusive` extension addresses this issue.

### F.13.2. Example Usage

```
CREATE EXTENSION daterange_inclusive;
SELECT daterange(' [2024-01-01,2024-06-01] ');
       daterange
-----
[2024-01-01,2024-06-02)

SELECT daterange_inclusive(' [2024-01-01,2024-06-01] ');
       daterange_inclusive
-----
[2024-01-01,2024-06-01]
```

## F.14. dblink

`dblink` is a module that supports connections to other Postgres Pro databases from within a database session.

See also [postgres\\_fdw](#), which provides roughly the same functionality using a more modern and standards-compliant infrastructure.

## dblink\_connect

`dblink_connect` — opens a persistent connection to a remote database

### Synopsis

```
dblink_connect(text connstr) returns text
dblink_connect(text connname, text connstr) returns text
```

### Description

`dblink_connect()` establishes a connection to a remote Postgres Pro database. The server and database to be contacted are identified through a standard libpq connection string. Optionally, a name can be assigned to the connection. Multiple named connections can be open at once, but only one unnamed connection is permitted at a time. The connection will persist until closed or until the database session is ended.

The connection string may also be the name of an existing foreign server. It is recommended to use the foreign-data wrapper `dblink_fdw` when defining the foreign server. See the example below, as well as [CREATE SERVER](#) and [CREATE USER MAPPING](#).

### Arguments

*connname*

The name to use for this connection; if omitted, an unnamed connection is opened, replacing any existing unnamed connection.

*connstr*

libpq-style connection info string, for example `hostaddr=127.0.0.1 port=5432 dbname=mydb user=postgres password=mypasswd options=-csearch_path=`. For details see [Section 36.1.1](#). Alternatively, the name of a foreign server.

### Return Value

Returns status, which is always OK (since any error causes the function to throw an error instead of returning).

### Notes

If untrusted users have access to a database that has not adopted a [secure schema usage pattern](#), begin each session by removing publicly-writable schemas from `search_path`. One could, for example, add `options=-csearch_path=` to *connstr*. This consideration is not specific to `dblink`; it applies to every interface for executing arbitrary SQL commands.

Only superusers may use `dblink_connect` to create non-password-authenticated connections. If non-superusers need this capability, use `dblink_connect_u` instead.

It is unwise to choose connection names that contain equal signs, as this opens a risk of confusion with connection info strings in other `dblink` functions.

### Examples

```
SELECT dblink_connect('dbname=postgres options=-csearch_path=');
 dblink_connect
-----
      OK
(1 row)

SELECT dblink_connect('myconn', 'dbname=postgres options=-csearch_path=');
```

Additional Supplied Modules  
and Extensions Shipped in  
postgrespro-ent-14-contrib

---

```
dblink_connect

```

## dblink\_connect\_u

`dblink_connect_u` — opens a persistent connection to a remote database, insecurely

### Synopsis

```
dblink_connect_u(text connstr) returns text  
dblink_connect_u(text connname, text connstr) returns text
```

### Description

`dblink_connect_u()` is identical to `dblink_connect()`, except that it will allow non-superusers to connect using any authentication method.

If the remote server selects an authentication method that does not involve a password, then impersonation and subsequent escalation of privileges can occur, because the session will appear to have originated from the user as which the local Postgres Pro server runs. Also, even if the remote server does demand a password, it is possible for the password to be supplied from the server environment, such as a `~/.pgpass` file belonging to the server's user. This opens not only a risk of impersonation, but the possibility of exposing a password to an untrustworthy remote server. Therefore, `dblink_connect_u()` is initially installed with all privileges revoked from `PUBLIC`, making it un-callable except by superusers. In some situations it may be appropriate to grant `EXECUTE` permission for `dblink_connect_u()` to specific users who are considered trustworthy, but this should be done with care. It is also recommended that any `~/.pgpass` file belonging to the server's user *not* contain any records specifying a wildcard host name.

For further details see `dblink_connect()`.

## dblink\_disconnect

`dblink_disconnect` — closes a persistent connection to a remote database

### Synopsis

```
dblink_disconnect() returns text  
dblink_disconnect(text connname) returns text
```

### Description

`dblink_disconnect()` closes a connection previously opened by `dblink_connect()`. The form with no arguments closes an unnamed connection.

### Arguments

*connname*

The name of a named connection to be closed.

### Return Value

Returns status, which is always `OK` (since any error causes the function to throw an error instead of returning).

### Examples

```
SELECT dblink_disconnect();  
 dblink_disconnect  
-----  
OK  
(1 row)  
  
SELECT dblink_disconnect('myconn');  
 dblink_disconnect  
-----  
OK  
(1 row)
```

## dblink

**dblink** — executes a query in a remote database

## Synopsis

```
dblink(text connname, text sql [, bool fail_on_error]) returns setof record
dblink(text connstr, text sql [, bool fail_on_error]) returns setof record
dblink(text sql [, bool fail_on_error]) returns setof record
```

## Description

**dblink** executes a query (usually a `SELECT`, but it can be any SQL statement that returns rows) in a remote database.

When two `text` arguments are given, the first one is first looked up as a persistent connection's name; if found, the command is executed on that connection. If not found, the first argument is treated as a connection info string as for `dblink_connect`, and the indicated connection is made just for the duration of this command.

## Arguments

*connname*

Name of the connection to use; omit this parameter to use the unnamed connection.

*connstr*

A connection info string, as previously described for `dblink_connect`.

*sql*

The SQL query that you wish to execute in the remote database, for example `select * from foo`.

*fail\_on\_error*

If true (the default when omitted) then an error thrown on the remote side of the connection causes an error to also be thrown locally. If false, the remote error is locally reported as a `NOTICE`, and the function returns no rows.

## Return Value

The function returns the row(s) produced by the query. Since **dblink** can be used with any query, it is declared to return `record`, rather than specifying any particular set of columns. This means that you must specify the expected set of columns in the calling query — otherwise Postgres Pro would not know what to expect. Here is an example:

```
SELECT *
FROM dblink('dbname=mydb options=-csearch_path=',
            'select proname, prosrc from pg_proc')
AS t1(proname name, prosrc text)
WHERE proname LIKE 'bytea%';
```

The “alias” part of the `FROM` clause must specify the column names and types that the function will return. (Specifying column names in an alias is actually standard SQL syntax, but specifying column types is a Postgres Pro extension.) This allows the system to understand what `*` should expand to, and what `proname` in the `WHERE` clause refers to, in advance of trying to execute the function. At run time, an error will be thrown if the actual query result from the remote database does not have the same number of columns shown in the `FROM` clause. The column names need not match, however, and **dblink** does not insist on exact type matches either. It will succeed so long as the returned data strings are valid input for the column type declared in the `FROM` clause.

## Notes

A convenient way to use `dblink` with predetermined queries is to create a view. This allows the column type information to be buried in the view, instead of having to spell it out in every query. For example,

```
CREATE VIEW myremote_pg_proc AS
  SELECT *
    FROM dblink('dbname=postgres options=-csearch_path=',
                'select proname, prosrc from pg_proc')
    AS t1(proname name, prosrc text);

SELECT * FROM myremote_pg_proc WHERE proname LIKE 'bytea%';
```

## Examples

```
SELECT * FROM dblink('dbname=postgres options=-csearch_path=',
                    'select proname, prosrc from pg_proc')
  AS t1(proname name, prosrc text) WHERE proname LIKE 'bytea%';

## dblink\_exec

`dblink_exec` — executes a command in a remote database

### Synopsis

```
dblink_exec(text connname, text sql [, bool fail_on_error]) returns text
dblink_exec(text connstr, text sql [, bool fail_on_error]) returns text
dblink_exec(text sql [, bool fail_on_error]) returns text
```

### Description

`dblink_exec` executes a command (that is, any SQL statement that doesn't return rows) in a remote database.

When two `text` arguments are given, the first one is first looked up as a persistent connection's name; if found, the command is executed on that connection. If not found, the first argument is treated as a connection info string as for `dblink_connect`, and the indicated connection is made just for the duration of this command.

### Arguments

*connname*

Name of the connection to use; omit this parameter to use the unnamed connection.

*connstr*

A connection info string, as previously described for `dblink_connect`.

*sql*

The SQL command that you wish to execute in the remote database, for example `insert into foo values (0, 'a', '{"a0","b0","c0"}')`.

*fail\_on\_error*

If true (the default when omitted) then an error thrown on the remote side of the connection causes an error to also be thrown locally. If false, the remote error is locally reported as a NOTICE, and the function's return value is set to `ERROR`.

### Return Value

Returns status, either the command's status string or `ERROR`.

### Examples

```
SELECT dblink_connect('dbname=dblink_test_standby');
 dblink_connect
-----
 OK
(1 row)

SELECT dblink_exec('insert into foo values(21, ''z'', ''{"a0","b0","c0"}'');');
 dblink_exec
-----
 INSERT 943366 1
(1 row)

SELECT dblink_connect('myconn', 'dbname=regression');
 dblink_connect
```

```
-----
OK
(1 row)

SELECT dblink_exec('myconn', 'insert into foo values(21, ''z'',
''{"a0","b0","c0"}'');');
      dblink_exec
-----

INSERT 6432584 1
(1 row)

SELECT dblink_exec('myconn', 'insert into pg_class values (''foo''),false);
NOTICE:  sql error
DETAIL:  ERROR:  null value in column "relnamespace" violates not-null constraint

      dblink_exec
-----

ERROR
(1 row)
```

## dblink\_open

`dblink_open` — opens a cursor in a remote database

## Synopsis

```
dblink_open(text cursorname, text sql [, bool fail_on_error]) returns text
dblink_open(text connname, text cursorname, text sql [, bool fail_on_error]) returns
text
```

## Description

`dblink_open()` opens a cursor in a remote database. The cursor can subsequently be manipulated with `dblink_fetch()` and `dblink_close()`.

## Arguments

*connname*

Name of the connection to use; omit this parameter to use the unnamed connection.

*cursorname*

The name to assign to this cursor.

*sql*

The `SELECT` statement that you wish to execute in the remote database, for example `select * from pg_class`.

*fail\_on\_error*

If true (the default when omitted) then an error thrown on the remote side of the connection causes an error to also be thrown locally. If false, the remote error is locally reported as a NOTICE, and the function's return value is set to `ERROR`.

## Return Value

Returns status, either `OK` or `ERROR`.

## Notes

Since a cursor can only persist within a transaction, `dblink_open` starts an explicit transaction block (`BEGIN`) on the remote side, if the remote side was not already within a transaction. This transaction will be closed again when the matching `dblink_close` is executed. Note that if you use `dblink_exec` to change data between `dblink_open` and `dblink_close`, and then an error occurs or you use `dblink_disconnect` before `dblink_close`, your change *will be lost* because the transaction will be aborted.

## Examples

```
SELECT dblink_connect('dbname=postgres options=-csearch_path=');
dblink_connect
-----
OK
(1 row)

SELECT dblink_open('foo', 'select proname, prosrc from pg_proc');
dblink_open
-----
OK
(1 row)
```

## dblink\_fetch

`dblink_fetch` — returns rows from an open cursor in a remote database

### Synopsis

```
dblink_fetch(text cursorname, int howmany [, bool fail_on_error]) returns setof record
dblink_fetch(text connname, text cursorname, int howmany [, bool fail_on_error])
returns setof record
```

### Description

`dblink_fetch` fetches rows from a cursor previously established by `dblink_open`.

### Arguments

*connname*

Name of the connection to use; omit this parameter to use the unnamed connection.

*cursorname*

The name of the cursor to fetch from.

*howmany*

The maximum number of rows to retrieve. The next *howmany* rows are fetched, starting at the current cursor position, moving forward. Once the cursor has reached its end, no more rows are produced.

*fail\_on\_error*

If true (the default when omitted) then an error thrown on the remote side of the connection causes an error to also be thrown locally. If false, the remote error is locally reported as a NOTICE, and the function returns no rows.

### Return Value

The function returns the row(s) fetched from the cursor. To use this function, you will need to specify the expected set of columns, as previously discussed for `dblink`.

### Notes

On a mismatch between the number of return columns specified in the `FROM` clause, and the actual number of columns returned by the remote cursor, an error will be thrown. In this event, the remote cursor is still advanced by as many rows as it would have been if the error had not occurred. The same is true for any other error occurring in the local query after the remote `FETCH` has been done.

### Examples

```
SELECT dblink_connect('dbname=postgres options=-csearch_path=');
dblink_connect
```

```
-----
OK
(1 row)
```

```
SELECT dblink_open('foo', 'select proname, prosrc from pg_proc where proname like
''bytea%'');
dblink_open
```

```
-----
OK
(1 row)
```

Additional Supplied Modules  
and Extensions Shipped in  
postgrespro-ent-14-contrib

---

```
SELECT * FROM dblink_fetch('foo', 5) AS (funcname name, source text);
 funcname | source
-----+-----
 byteacat | byteacat
 byteacmp | byteacmp
 byteaeq  | byteaeq
 byteage  | byteage
 byteagt  | byteagt
(5 rows)
```

```
SELECT * FROM dblink_fetch('foo', 5) AS (funcname name, source text);
 funcname | source
-----+-----
 byteain  | byteain
 byteale  | byteale
 bytealike| bytealike
 bytealt  | bytealt
 byteane  | byteane
(5 rows)
```

```
SELECT * FROM dblink_fetch('foo', 5) AS (funcname name, source text);
 funcname | source
-----+-----
 byteanlike| byteanlike
 byteaout  | byteaout
(2 rows)
```

```
SELECT * FROM dblink_fetch('foo', 5) AS (funcname name, source text);
 funcname | source
-----+-----
(0 rows)
```

## dblink\_close

`dblink_close` — closes a cursor in a remote database

## Synopsis

```
dblink_close(text cursorname [, bool fail_on_error]) returns text
dblink_close(text connname, text cursorname [, bool fail_on_error]) returns text
```

## Description

`dblink_close` closes a cursor previously opened with `dblink_open`.

## Arguments

*connname*

Name of the connection to use; omit this parameter to use the unnamed connection.

*cursorname*

The name of the cursor to close.

*fail\_on\_error*

If true (the default when omitted) then an error thrown on the remote side of the connection causes an error to also be thrown locally. If false, the remote error is locally reported as a NOTICE, and the function's return value is set to `ERROR`.

## Return Value

Returns status, either `OK` or `ERROR`.

## Notes

If `dblink_open` started an explicit transaction block, and this is the last remaining open cursor in this connection, `dblink_close` will issue the matching `COMMIT`.

## Examples

```
SELECT dblink_connect('dbname=postgres options=-csearch_path=');
 dblink_connect
-----
 OK
(1 row)

SELECT dblink_open('foo', 'select proname, prosrc from pg_proc');
 dblink_open
-----
 OK
(1 row)

SELECT dblink_close('foo');
 dblink_close
-----
 OK
(1 row)
```

## **dblink\_get\_connections**

`dblink_get_connections` — returns the names of all open named dblink connections

### **Synopsis**

```
dblink_get_connections() returns text[]
```

### **Description**

`dblink_get_connections` returns an array of the names of all open named dblink connections.

### **Return Value**

Returns a text array of connection names, or NULL if none.

### **Examples**

```
SELECT dblink_get_connections();
```

## **dblink\_error\_message**

`dblink_error_message` — gets last error message on the named connection

### **Synopsis**

```
dblink_error_message(text connname) returns text
```

### **Description**

`dblink_error_message` fetches the most recent remote error message for a given connection.

### **Arguments**

*connname*

Name of the connection to use.

### **Return Value**

Returns last error message, or OK if there has been no error in this connection.

### **Notes**

When asynchronous queries are initiated by `dblink_send_query`, the error message associated with the connection might not get updated until the server's response message is consumed. This typically means that `dblink_is_busy` or `dblink_get_result` should be called prior to `dblink_error_message`, so that any error generated by the asynchronous query will be visible.

### **Examples**

```
SELECT dblink_error_message('dtest1');
```

## dblink\_send\_query

`dblink_send_query` — sends an async query to a remote database

### Synopsis

```
dblink_send_query(text connname, text sql) returns int
```

### Description

`dblink_send_query` sends a query to be executed asynchronously, that is, without immediately waiting for the result. There must not be an async query already in progress on the connection.

After successfully dispatching an async query, completion status can be checked with `dblink_is_busy`, and the results are ultimately collected with `dblink_get_result`. It is also possible to attempt to cancel an active async query using `dblink_cancel_query`.

### Arguments

*connname*

Name of the connection to use.

*sql*

The SQL statement that you wish to execute in the remote database, for example `select * from pg_class`.

### Return Value

Returns 1 if the query was successfully dispatched, 0 otherwise.

### Examples

```
SELECT dblink_send_query('dtest1', 'SELECT * FROM foo WHERE f1 < 3');
```

## **dblink\_is\_busy**

`dblink_is_busy` — checks if connection is busy with an async query

### **Synopsis**

```
dblink_is_busy(text connname) returns int
```

### **Description**

`dblink_is_busy` tests whether an async query is in progress.

### **Arguments**

*connname*

Name of the connection to check.

### **Return Value**

Returns 1 if connection is busy, 0 if it is not busy. If this function returns 0, it is guaranteed that `dblink_get_result` will not block.

### **Examples**

```
SELECT dblink_is_busy('dtest1');
```

## dblink\_get\_notify

dblink\_get\_notify — retrieve async notifications on a connection

### Synopsis

```
dblink_get_notify() returns setof (notify_name text, be_pid int, extra text)
dblink_get_notify(text connname) returns setof (notify_name text, be_pid int, extra
text)
```

### Description

dblink\_get\_notify retrieves notifications on either the unnamed connection, or on a named connection if specified. To receive notifications via dblink, LISTEN must first be issued, using dblink\_exec. For details see [LISTEN](#) and [NOTIFY](#).

### Arguments

*connname*

The name of a named connection to get notifications on.

### Return Value

Returns setof (notify\_name text, be\_pid int, extra text), or an empty set if none.

### Examples

```
SELECT dblink_exec('LISTEN virtual');
 dblink_exec
-----
LISTEN
(1 row)
```

```
SELECT * FROM dblink_get_notify();
 notify_name | be_pid | extra
-----+-----+-----
(0 rows)
```

```
NOTIFY virtual;
NOTIFY
```

```
SELECT * FROM dblink_get_notify();
 notify_name | be_pid | extra
-----+-----+-----
virtual      |    1229 |
(1 row)
```

## dblink\_get\_result

`dblink_get_result` — gets an async query result

## Synopsis

```
dblink_get_result(text connname [, bool fail_on_error]) returns setof record
```

## Description

`dblink_get_result` collects the results of an asynchronous query previously sent with `dblink_send_query`. If the query is not already completed, `dblink_get_result` will wait until it is.

## Arguments

*connname*

Name of the connection to use.

*fail\_on\_error*

If true (the default when omitted) then an error thrown on the remote side of the connection causes an error to also be thrown locally. If false, the remote error is locally reported as a NOTICE, and the function returns no rows.

## Return Value

For an async query (that is, an SQL statement returning rows), the function returns the row(s) produced by the query. To use this function, you will need to specify the expected set of columns, as previously discussed for `dblink`.

For an async command (that is, an SQL statement not returning rows), the function returns a single row with a single text column containing the command's status string. It is still necessary to specify that the result will have a single text column in the calling `FROM` clause.

## Notes

This function *must* be called if `dblink_send_query` returned 1. It must be called once for each query sent, and one additional time to obtain an empty set result, before the connection can be used again.

When using `dblink_send_query` and `dblink_get_result`, `dblink` fetches the entire remote query result before returning any of it to the local query processor. If the query returns a large number of rows, this can result in transient memory bloat in the local session. It may be better to open such a query as a cursor with `dblink_open` and then fetch a manageable number of rows at a time. Alternatively, use plain `dblink()`, which avoids memory bloat by spooling large result sets to disk.

## Examples

```
contrib_regression=# SELECT dblink_connect('dtest1', 'dbname=contrib_regression');
dblink_connect
-----
OK
(1 row)

contrib_regression=# SELECT * FROM
contrib_regression-# dblink_send_query('dtest1', 'select * from foo where f1 < 3') AS
t1;
t1
----
1
(1 row)
```

```
contrib_regression=# SELECT * FROM dblink_get_result('dtest1') AS t1(f1 int, f2 text,
f3 text[]);
 f1 | f2 |      f3
-----+-----+-----
  0 | a  | {a0,b0,c0}
  1 | b  | {a1,b1,c1}
  2 | c  | {a2,b2,c2}
(3 rows)
```

```
contrib_regression=# SELECT * FROM dblink_get_result('dtest1') AS t1(f1 int, f2 text,
f3 text[]);
 f1 | f2 | f3
-----+-----+-----
(0 rows)
```

```
contrib_regression=# SELECT * FROM
contrib_regression=# dblink_send_query('dtest1', 'select * from foo where f1 < 3;
select * from foo where f1 > 6') AS t1;
t1
----
  1
(1 row)
```

```
contrib_regression=# SELECT * FROM dblink_get_result('dtest1') AS t1(f1 int, f2 text,
f3 text[]);
 f1 | f2 |      f3
-----+-----+-----
  0 | a  | {a0,b0,c0}
  1 | b  | {a1,b1,c1}
  2 | c  | {a2,b2,c2}
(3 rows)
```

```
contrib_regression=# SELECT * FROM dblink_get_result('dtest1') AS t1(f1 int, f2 text,
f3 text[]);
 f1 | f2 |      f3
-----+-----+-----
  7 | h  | {a7,b7,c7}
  8 | i  | {a8,b8,c8}
  9 | j  | {a9,b9,c9}
 10 | k  | {a10,b10,c10}
(4 rows)
```

```
contrib_regression=# SELECT * FROM dblink_get_result('dtest1') AS t1(f1 int, f2 text,
f3 text[]);
 f1 | f2 | f3
-----+-----+-----
(0 rows)
```

## **dblink\_cancel\_query**

`dblink_cancel_query` — cancels any active query on the named connection

### **Synopsis**

```
dblink_cancel_query(text connname) returns text
```

### **Description**

`dblink_cancel_query` attempts to cancel any query that is in progress on the named connection. Note that this is not certain to succeed (since, for example, the remote query might already have finished). A cancel request simply improves the odds that the query will fail soon. You must still complete the normal query protocol, for example by calling `dblink_get_result`.

### **Arguments**

*connname*

Name of the connection to use.

### **Return Value**

Returns `OK` if the cancel request has been sent, or the text of an error message on failure.

### **Examples**

```
SELECT dblink_cancel_query('dtest1');
```

## dblink\_get\_pkey

`dblink_get_pkey` — returns the positions and field names of a relation's primary key fields

## Synopsis

`dblink_get_pkey(text relname)` returns `setof dblink_pkey_results`

## Description

`dblink_get_pkey` provides information about the primary key of a relation in the local database. This is sometimes useful in generating queries to be sent to remote databases.

## Arguments

*relname*

Name of a local relation, for example `foo` or `myschema.mytab`. Include double quotes if the name is mixed-case or contains special characters, for example `"FooBar"`; without quotes, the string will be folded to lower case.

## Return Value

Returns one row for each primary key field, or no rows if the relation has no primary key. The result row type is defined as

```
CREATE TYPE dblink_pkey_results AS (position int, colname text);
```

The `position` column simply runs from 1 to *N*; it is the number of the field within the primary key, not the number within the table's columns.

## Examples

```
CREATE TABLE foobar (  
    f1 int,  
    f2 int,  
    f3 int,  
    PRIMARY KEY (f1, f2, f3)  
);  
CREATE TABLE  
  
SELECT * FROM dblink_get_pkey('foobar');  
 position | colname  
-----+-----  
        1 | f1  
        2 | f2  
        3 | f3  
(3 rows)
```

## dblink\_build\_sql\_insert

`dblink_build_sql_insert` — builds an `INSERT` statement using a local tuple, replacing the primary key field values with alternative supplied values

### Synopsis

```
dblink_build_sql_insert(text relname,  
                        int2vector primary_key_attnums,  
                        integer num_primary_key_atts,  
                        text[] src_pk_att_vals_array,  
                        text[] tgt_pk_att_vals_array) returns text
```

### Description

`dblink_build_sql_insert` can be useful in doing selective replication of a local table to a remote database. It selects a row from the local table based on primary key, and then builds an SQL `INSERT` command that will duplicate that row, but with the primary key values replaced by the values in the last argument. (To make an exact copy of the row, just specify the same values for the last two arguments.)

### Arguments

*relname*

Name of a local relation, for example `foo` or `myschema.mytab`. Include double quotes if the name is mixed-case or contains special characters, for example `"FooBar"`; without quotes, the string will be folded to lower case.

*primary\_key\_attnums*

Attribute numbers (1-based) of the primary key fields, for example `1 2`.

*num\_primary\_key\_atts*

The number of primary key fields.

*src\_pk\_att\_vals\_array*

Values of the primary key fields to be used to look up the local tuple. Each field is represented in text form. An error is thrown if there is no local row with these primary key values.

*tgt\_pk\_att\_vals\_array*

Values of the primary key fields to be placed in the resulting `INSERT` command. Each field is represented in text form.

### Return Value

Returns the requested SQL statement as text.

### Notes

As of PostgreSQL 9.0, the attribute numbers in *primary\_key\_attnums* are interpreted as logical column numbers, corresponding to the column's position in `SELECT * FROM relname`. Previous versions interpreted the numbers as physical column positions. There is a difference if any column(s) to the left of the indicated column have been dropped during the lifetime of the table.

### Examples

```
SELECT dblink_build_sql_insert('foo', '1 2', 2, '{"1", "a"}', '{"1", "b''a"}');  
       dblink_build_sql_insert
```

-----

Additional Supplied Modules  
and Extensions Shipped in  
postgrespro-ent-14-contrib

---

```
INSERT INTO foo(f1,f2,f3) VALUES('1','b' 'a','1')
(1 row)
```

## dblink\_build\_sql\_delete

`dblink_build_sql_delete` — builds a DELETE statement using supplied values for primary key field values

### Synopsis

```
dblink_build_sql_delete(text relname,  
                        int2vector primary_key_attnums,  
                        integer num_primary_key_atts,  
                        text[] tgt_pk_att_vals_array) returns text
```

### Description

`dblink_build_sql_delete` can be useful in doing selective replication of a local table to a remote database. It builds an SQL DELETE command that will delete the row with the given primary key values.

### Arguments

*relname*

Name of a local relation, for example `foo` or `myschema.mytab`. Include double quotes if the name is mixed-case or contains special characters, for example `"FooBar"`; without quotes, the string will be folded to lower case.

*primary\_key\_attnums*

Attribute numbers (1-based) of the primary key fields, for example `1 2`.

*num\_primary\_key\_atts*

The number of primary key fields.

*tgt\_pk\_att\_vals\_array*

Values of the primary key fields to be used in the resulting DELETE command. Each field is represented in text form.

### Return Value

Returns the requested SQL statement as text.

### Notes

As of PostgreSQL 9.0, the attribute numbers in *primary\_key\_attnums* are interpreted as logical column numbers, corresponding to the column's position in `SELECT * FROM relname`. Previous versions interpreted the numbers as physical column positions. There is a difference if any column(s) to the left of the indicated column have been dropped during the lifetime of the table.

### Examples

```
SELECT dblink_build_sql_delete('MyFoo', '1 2', 2, '{"1", "b"}');  
      dblink_build_sql_delete  
-----  
DELETE FROM "MyFoo" WHERE f1='1' AND f2='b'  
(1 row)
```

## dblink\_build\_sql\_update

`dblink_build_sql_update` — builds an UPDATE statement using a local tuple, replacing the primary key field values with alternative supplied values

### Synopsis

```
dblink_build_sql_update(text relname,  
                        int2vector primary_key_attnums,  
                        integer num_primary_key_atts,  
                        text[] src_pk_att_vals_array,  
                        text[] tgt_pk_att_vals_array) returns text
```

### Description

`dblink_build_sql_update` can be useful in doing selective replication of a local table to a remote database. It selects a row from the local table based on primary key, and then builds an SQL UPDATE command that will duplicate that row, but with the primary key values replaced by the values in the last argument. (To make an exact copy of the row, just specify the same values for the last two arguments.) The UPDATE command always assigns all fields of the row — the main difference between this and `dblink_build_sql_insert` is that it's assumed that the target row already exists in the remote table.

### Arguments

*relname*

Name of a local relation, for example `foo` or `myschema.mytab`. Include double quotes if the name is mixed-case or contains special characters, for example `"FooBar"`; without quotes, the string will be folded to lower case.

*primary\_key\_attnums*

Attribute numbers (1-based) of the primary key fields, for example `1 2`.

*num\_primary\_key\_atts*

The number of primary key fields.

*src\_pk\_att\_vals\_array*

Values of the primary key fields to be used to look up the local tuple. Each field is represented in text form. An error is thrown if there is no local row with these primary key values.

*tgt\_pk\_att\_vals\_array*

Values of the primary key fields to be placed in the resulting UPDATE command. Each field is represented in text form.

### Return Value

Returns the requested SQL statement as text.

### Notes

As of PostgreSQL 9.0, the attribute numbers in *primary\_key\_attnums* are interpreted as logical column numbers, corresponding to the column's position in `SELECT * FROM relname`. Previous versions interpreted the numbers as physical column positions. There is a difference if any column(s) to the left of the indicated column have been dropped during the lifetime of the table.

### Examples

```
SELECT dblink_build_sql_update('foo', '1 2', 2, '{"1", "a"}', '{"1", "b"}');  
       dblink_build_sql_update
```

-----

```
UPDATE foo SET f1='1',f2='b',f3='1' WHERE f1='1' AND f2='b'
(1 row)
```

## F.15. dict\_int

`dict_int` is an example of an add-on dictionary template for full-text search. The motivation for this example dictionary is to control the indexing of integers (signed and unsigned), allowing such numbers to be indexed while preventing excessive growth in the number of unique words, which greatly affects the performance of searching.

This module is considered “trusted”, that is, it can be installed by non-superusers who have `CREATE` privilege on the current database.

### F.15.1. Configuration

The dictionary accepts three options:

- The `maxlen` parameter specifies the maximum number of digits allowed in an integer word. The default value is 6.
- The `rejectlong` parameter specifies whether an overlength integer should be truncated or ignored. If `rejectlong` is `false` (the default), the dictionary returns the first `maxlen` digits of the integer. If `rejectlong` is `true`, the dictionary treats an overlength integer as a stop word, so that it will not be indexed. Note that this also means that such an integer cannot be searched for.
- The `absval` parameter specifies whether leading “+” or “-” signs should be removed from integer words. The default is `false`. When `true`, the sign is removed before `maxlen` is applied.

### F.15.2. Usage

Installing the `dict_int` extension creates a text search template `intdict_template` and a dictionary `intdict` based on it, with the default parameters. You can alter the parameters, for example

```
mydb# ALTER TEXT SEARCH DICTIONARY intdict (MAXLEN = 4, REJECTLONG = true);
ALTER TEXT SEARCH DICTIONARY
```

or create new dictionaries based on the template.

To test the dictionary, you can try

```
mydb# select ts_lexize('intdict', '12345678');
 ts_lexize
-----
 {123456}
```

but real-world usage will involve including it in a text search configuration as described in [Chapter 12](#). That might look like this:

```
ALTER TEXT SEARCH CONFIGURATION english
    ALTER MAPPING FOR int, uint WITH intdict;
```

## F.16. dict\_xsyn

`dict_xsyn` (Extended Synonym Dictionary) is an example of an add-on dictionary template for full-text search. This dictionary type replaces words with groups of their synonyms, and so makes it possible to search for a word using any of its synonyms.

### F.16.1. Configuration

A `dict_xsyn` dictionary accepts the following options:

- `matchorig` controls whether the original word is accepted by the dictionary. Default is `true`.
- `matchsynonyms` controls whether the synonyms are accepted by the dictionary. Default is `false`.
- `keeporig` controls whether the original word is included in the dictionary's output. Default is `true`.

- `keepsynonyms` controls whether the synonyms are included in the dictionary's output. Default is `true`.
- `rules` is the base name of the file containing the list of synonyms. This file must be stored in `$$SHAREDIR/tsearch_data/` (where `$$SHAREDIR` means the Postgres Pro installation's shared-data directory). Its name must end in `.rules` (which is not to be included in the `rules` parameter).

The rules file has the following format:

- Each line represents a group of synonyms for a single word, which is given first on the line. Synonyms are separated by whitespace, thus:  

```
word syn1 syn2 syn3
```
- The sharp (#) sign is a comment delimiter. It may appear at any position in a line. The rest of the line will be skipped.

Look at `xsyn_sample.rules`, which is installed in `$$SHAREDIR/tsearch_data/`, for an example.

## F.16.2. Usage

Installing the `dict_xsyn` extension creates a text search template `xsyn_template` and a dictionary `xsyn` based on it, with default parameters. You can alter the parameters, for example

```
mydb# ALTER TEXT SEARCH DICTIONARY xsyn (RULES='my_rules', KEEPORIG=false);
ALTER TEXT SEARCH DICTIONARY
```

or create new dictionaries based on the template.

To test the dictionary, you can try

```
mydb=# SELECT ts_lexize('xsyn', 'word');
         ts_lexize
-----
{syn1,syn2,syn3}
```

```
mydb# ALTER TEXT SEARCH DICTIONARY xsyn (RULES='my_rules', KEEPORIG=true);
ALTER TEXT SEARCH DICTIONARY
```

```
mydb=# SELECT ts_lexize('xsyn', 'word');
         ts_lexize
-----
{word,syn1,syn2,syn3}
```

```
mydb# ALTER TEXT SEARCH DICTIONARY xsyn (RULES='my_rules', KEEPORIG=false,
MATCHSYNONYMS=true);
ALTER TEXT SEARCH DICTIONARY
```

```
mydb=# SELECT ts_lexize('xsyn', 'syn1');
         ts_lexize
-----
{syn1,syn2,syn3}
```

```
mydb# ALTER TEXT SEARCH DICTIONARY xsyn (RULES='my_rules', KEEPORIG=true,
MATCHORIG=false, KEEPSYNONYMS=false);
ALTER TEXT SEARCH DICTIONARY
```

```
mydb=# SELECT ts_lexize('xsyn', 'syn1');
         ts_lexize
-----
{word}
```

Real-world usage will involve including it in a text search configuration as described in [Chapter 12](#). That might look like this:

```
ALTER TEXT SEARCH CONFIGURATION english
  ALTER MAPPING FOR word, asciiword WITH xsyn, english_stem;
```

## F.17. dump\_stat

The `dump_stat` module provides functions that allow you to backup and recover the contents of the `pg_statistic` table. When performing a dump/restore, you can use `dump_stat` to migrate the original statistics to the new server instead of running the `ANALYZE` command for the whole database cluster, which can significantly reduce downtime for large databases. The `dump_statistic` function generates `INSERT` statements which can later be applied to a compatible database. To successfully restore statistical data, you must install the extension on both the original and the recipient servers since these statements rely on the provided `dump_stat` functions.

Note that the definition of the `pg_statistic` table might change occasionally, which means that generated dump might be incompatible with future releases of Postgres Pro.

### F.17.1. Installation

The `dump_stat` extension is included into Postgres Pro. Once you have Postgres Pro installed, you must execute the `CREATE EXTENSION` command to enable `dump_stat`, as follows:

```
CREATE EXTENSION dump_stat;
```

### F.17.2. Functions

`anyarray_to_text(array anyarray)` returns text

Returns the given array as text.

`dump_statistic()` returns setof text

`dump_statistic` dumps the contents of the `pg_statistic` system catalog. It produces an `INSERT` statement per each tuple of the `pg_statistic`, excluding the ones that contain statistical data for tables in the `information_schema` and `pg_catalog` schemas.

The `INSERT` statement takes form of

```
WITH upsert as (
  UPDATE pg_catalog.pg_statistic SET column_name = expression [, ...]
  WHERE starelid = t_relname::regclass
    AND to_attnum(t_relname, staattnum) = t_attnum
    AND to_atttype(t_relname, staattnum) = t_atttype
    AND stainherit = t_stainherit
  RETURNING *)
```

```
ins as (
  SELECT expression [, ...]
  WHERE NOT EXISTS (SELECT * FROM upsert)
    AND to_attnum(t_relname, t_attnum) IS NOT NULL
    AND to_atttype(t_relname, t_attnum) = t_atttype)
INSERT INTO pg_catalog.pg_statistic SELECT * FROM ins;
```

where *expression* can be one of:

```
array_in(array_text, type_name::regtype::oid, -1)
value::type_name
```

To save the produced statements, redirect the `psql` output into a file using standard `psql` options. For details on the available `psql` options, see [psql](#). Meta-commands starting with a backslash are not supported.

For example, to save statistics for the `dbname` database into a `dump_stat.sql` file, run:

```
$ psql -XAtq -c "SELECT dump_statistic()" dbname > dump_stat.sql
```

`dump_statistic(schema_name text)` returns setof text

`dump_statistic` dumps the contents of the `pg_statistic` system catalog. It produces an INSERT statement per each tuple of the `pg_statistic` that relates to some table in the `schema_name` schema.

`dump_statistic(schema_name text, table_name text)` returns setof text

`dump_statistic` dumps the contents of the `pg_statistic` system catalog. It produces an INSERT statement per each tuple of the `pg_statistic` that relates to the specified `schema_name.table_name` table.

`dump_statistic(relation regclass)` returns setof text

`dump_statistic` dumps the contents of the `pg_statistic` system catalog. It produces an INSERT statement per each tuple of the `pg_statistic` that contains statistical data for the specified relation.

`to_schema_qualified_operator(opid oid)` returns text

Fetches the schema-qualified operator name by operator id `opid`. For example:

```
test=# SELECT to_schema_qualified_operator('+(int,int)::regoperator);
       to_schema_qualified_operator
-----
pg_catalog.+(pg_catalog.int4, pg_catalog.int4)
(1 row)
```

`to_schema_qualified_type(typid oid)` returns text

Fetches the schema-qualified type name by type id `typid`.

`to_schema_qualified_relation(relid oid)` returns text

Fetches the schema-qualified relation name by relation id `relid`.

`anyarray_elemtype(arr anyarray)` returns oid

Returns the element type of the given array as oid. For example:

```
test=# SELECT anyarray_elemtype(array_in('{1,2,3}', 'int'::regtype, -1));
       anyarray_elemtype
-----
                23
(1 row)
```

`to_attname(relation regclass, colnum int2)` returns text

Given a relation name `relation` and a column number `colnum`, returns the column name as text.

`to_attnum(relation regclass, col text)` returns int2

Given a relation name `relation` and a column name `col`, returns the column number as int2.

`to_atttype(relation regclass, col text)` returns text

Given a relation name `relation` and a column name `col`, returns the schema-qualified column type as text.

`to_atttype(relation regclass, colnum int2)` returns text

Given a relation name `relation` and a column number `colnum`, returns the schema-qualified column type as text.

`to_namespace(nsp text)` returns oid

`to_namespace` duplicates the behavior of the cast to the `regnamespace` type, which is not present in the PostgreSQL 9.4 release (and prior releases). This function returns the oid of the given schema.

---

`get_namespace(relation oid)` returns `oid`

`get_namespace` returns the schema of the given relation as `oid`.

## F.18. earthdistance

The `earthdistance` module provides two different approaches to calculating great circle distances on the surface of the Earth. The one described first depends on the `cube` module. The second one is based on the built-in `point` data type, using longitude and latitude for the coordinates.

In this module, the Earth is assumed to be perfectly spherical. (If that's too inaccurate for you, you might want to look at the [PostGIS](#) project.)

The `cube` module must be installed before `earthdistance` can be installed (although you can use the `CASCADE` option of `CREATE EXTENSION` to install both in one command).

### Caution

It is strongly recommended that `earthdistance` and `cube` be installed in the same schema, and that that schema be one for which `CREATE` privilege has not been and will not be granted to any untrusted users. Otherwise there are installation-time security hazards if `earthdistance`'s schema contains objects defined by a hostile user. Furthermore, when using `earthdistance`'s functions after installation, the entire search path should contain only trusted schemas.

### F.18.1. Cube-Based Earth Distances

Data is stored in cubes that are points (both corners are the same) using 3 coordinates representing the `x`, `y`, and `z` distance from the center of the Earth. A domain `earth` over `cube` is provided, which includes constraint checks that the value meets these restrictions and is reasonably close to the actual surface of the Earth.

The radius of the Earth is obtained from the `earth()` function. It is given in meters. But by changing this one function you can change the module to use some other units, or to use a different value of the radius that you feel is more appropriate.

This package has applications to astronomical databases as well. Astronomers will probably want to change `earth()` to return a radius of `180/pi()` so that distances are in degrees.

Functions are provided to support input in latitude and longitude (in degrees), to support output of latitude and longitude, to calculate the great circle distance between two points and to easily specify a bounding box usable for index searches.

The provided functions are shown in [Table F.15](#).

**Table F.15. Cube-Based Earthdistance Functions**

| Function                                            | Description                                                                                                                                   |
|-----------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------|
| <code>earth () → float8</code>                      | Returns the assumed radius of the Earth.                                                                                                      |
| <code>sec_to_gc ( float8 ) → float8</code>          | Converts the normal straight line (secant) distance between two points on the surface of the Earth to the great circle distance between them. |
| <code>gc_to_sec ( float8 ) → float8</code>          | Converts the great circle distance between two points on the surface of the Earth to the normal straight line (secant) distance between them. |
| <code>ll_to_earth ( float8, float8 ) → earth</code> |                                                                                                                                               |

| Function                                              | Description                                                                                                                                                                                                                                                                                                                                 |
|-------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                                       | Returns the location of a point on the surface of the Earth given its latitude (argument 1) and longitude (argument 2) in degrees.                                                                                                                                                                                                          |
| <code>latitude ( earth ) → float8</code>              | Returns the latitude in degrees of a point on the surface of the Earth.                                                                                                                                                                                                                                                                     |
| <code>longitude ( earth ) → float8</code>             | Returns the longitude in degrees of a point on the surface of the Earth.                                                                                                                                                                                                                                                                    |
| <code>earth_distance ( earth, earth ) → float8</code> | Returns the great circle distance between two points on the surface of the Earth.                                                                                                                                                                                                                                                           |
| <code>earth_box ( earth, float8 ) → cube</code>       | Returns a box suitable for an indexed search using the <code>cube @&gt;</code> operator for points within a given great circle distance of a location. Some points in this box are further than the specified great circle distance from the location, so a second check using <code>earth_distance</code> should be included in the query. |

## F.18.2. Point-Based Earth Distances

The second part of the module relies on representing Earth locations as values of type `point`, in which the first component is taken to represent longitude in degrees, and the second component is taken to represent latitude in degrees. Points are taken as (longitude, latitude) and not vice versa because longitude is closer to the intuitive idea of x-axis and latitude to y-axis.

A single operator is provided, shown in [Table F.16](#).

**Table F.16. Point-Based Earthdistance Operators**

| Operator                                    | Description                                                                       |
|---------------------------------------------|-----------------------------------------------------------------------------------|
| <code>point &lt;@&gt; point → float8</code> | Computes the distance in statute miles between two points on the Earth's surface. |

Note that unlike the `cube`-based part of the module, units are hardwired here: changing the `earth()` function will not affect the results of this operator.

One disadvantage of the longitude/latitude representation is that you need to be careful about the edge conditions near the poles and near +/- 180 degrees of longitude. The `cube`-based representation avoids these discontinuities.

## F.19. fasttrun

The `fasttrun` module provides transaction unsafe function to truncate temporary tables without growing `pg_class` size.

This module is required for 1C Enterprise support.

Fast truncate operation is not transactional, so its results cannot be rolled back and become immediately visible in all sessions regardless of isolation level.

### F.19.1. Function

There is a function call example:

```
select fasttruncate('TABLE_NAME');
```

### F.19.2. Test example

For tests you can use this example:

```
create or replace function f() returns void as $$
begin
    for i in 1..1000
        loop
            PERFORM fasttruncate('tt1');
        end loop;
    end;
$$ language plpgsql;
```

### F.19.3. Authors

Teodor Sigaev <teodor@sigaev.ru>

## F.20. file\_fdw

The `file_fdw` module provides the foreign-data wrapper `file_fdw`, which can be used to access data files in the server's file system, or to execute programs on the server and read their output. The data file or program output must be in a format that can be read by `COPY FROM`; see [COPY](#) for details. Access to data files is currently read-only.

A foreign table created using this wrapper can have the following options:

`filename`

Specifies the file to be read. Relative paths are relative to the data directory. Either `filename` or `program` must be specified, but not both.

`program`

Specifies the command to be executed. The standard output of this command will be read as though `COPY FROM PROGRAM` were used. Either `program` or `filename` must be specified, but not both.

`format`

Specifies the data format, the same as `COPY`'s `FORMAT` option.

`header`

Specifies whether the data has a header line, the same as `COPY`'s `HEADER` option.

`delimiter`

Specifies the data delimiter character, the same as `COPY`'s `DELIMITER` option.

`quote`

Specifies the data quote character, the same as `COPY`'s `QUOTE` option.

`escape`

Specifies the data escape character, the same as `COPY`'s `ESCAPE` option.

`null`

Specifies the data null string, the same as `COPY`'s `NULL` option.

`encoding`

Specifies the data encoding, the same as `COPY`'s `ENCODING` option.

Note that while `COPY` allows options such as `HEADER` to be specified without a corresponding value, the foreign table option syntax requires a value to be present in all cases. To activate `COPY` options typically written without a value, you can pass the value `TRUE`, since all such options are Booleans.

A column of a foreign table created using this wrapper can have the following options:

`force_not_null`

This is a Boolean option. If true, it specifies that values of the column should not be matched against the null string (that is, the table-level `null` option). This has the same effect as listing the column in COPY's `FORCE_NOT_NULL` option.

`force_null`

This is a Boolean option. If true, it specifies that values of the column which match the null string are returned as `NULL` even if the value is quoted. Without this option, only unquoted values matching the null string are returned as `NULL`. This has the same effect as listing the column in COPY's `FORCE_NULL` option.

COPY's `FORCE_QUOTE` option is currently not supported by `file_fdw`.

These options can only be specified for a foreign table or its columns, not in the options of the `file_fdw` foreign-data wrapper, nor in the options of a server or user mapping using the wrapper.

Changing table-level options requires being a superuser or having the privileges of the role `pg_read_server_files` (to use a filename) or the role `pg_execute_server_program` (to use a program), for security reasons: only certain users should be able to control which file is read or which program is run. In principle regular users could be allowed to change the other options, but that's not supported at present.

When specifying the `program` option, keep in mind that the option string is executed by the shell. If you need to pass any arguments to the command that come from an untrusted source, you must be careful to strip or escape any characters that might have special meaning to the shell. For security reasons, it is best to use a fixed command string, or at least avoid passing any user input in it.

For a foreign table using `file_fdw`, `EXPLAIN` shows the name of the file to be read or program to be run. For a file, unless `COSTS OFF` is specified, the file size (in bytes) is shown as well.

### Example F.3. Create a Foreign Table for Postgres Pro CSV Logs

One of the obvious uses for `file_fdw` is to make the Postgres Pro activity log available as a table for querying. To do this, first you must be [logging to a CSV file](#), which here we will call `pglog.csv`. First, install `file_fdw` as an extension:

```
CREATE EXTENSION file_fdw;
```

Then create a foreign server:

```
CREATE SERVER pglog FOREIGN DATA WRAPPER file_fdw;
```

Now you are ready to create the foreign data table. Using the `CREATE FOREIGN TABLE` command, you will need to define the columns for the table, the CSV file name, and its format:

```
CREATE FOREIGN TABLE pglog (  
    log_time timestamp(3) with time zone,  
    user_name text,  
    database_name text,  
    process_id integer,  
    connection_from text,  
    session_id text,  
    session_line_num bigint,  
    command_tag text,  
    session_start_time timestamp with time zone,  
    virtual_transaction_id text,  
    transaction_id bigint,  
    error_severity text,  
    sql_state_code text,  
    message text,  
    detail text,  
    hint text,
```

```
internal_query text,  
internal_query_pos integer,  
context text,  
query text,  
query_pos integer,  
location text,  
application_name text,  
backend_type text,  
leader_pid integer,  
query_id bigint  
) SERVER pglog  
OPTIONS ( filename 'log/pglog.csv', format 'csv' );
```

That's it — now you can query your log directly. In production, of course, you would need to define some way to deal with log rotation.

## F.21. fulleq

The `fulleq` module provides additional equivalence operator for compatibility with Microsoft SQL Server.

This module is required for 1C Enterprise support.

### F.21.1. Overview

The Postgres Pro equivalence operator is defined to return NULL when both operands are NULLs. However, the Microsoft SQL Servers family traditionally defines other semantic for equivalence operator, where operator returns TRUE in the case of both nulled operands. This module provides such operator with MS SQL semantic.

### F.21.2. Operator `fulleq`

The `==` operator is defined for the following data types:

- `bool`
- `bytea`
- `char`
- `name`
- `int2`
- `int4`
- `int8`
- `int2vector`
- `text`
- `oid`
- `xid`
- `cid`
- `oidvector`
- `float4`
- `float8`
- `abstime`
- `reltime`
- `macaddr`
- `inet`

- cidr
- varchar
- date
- time
- timestamp
- timestamptz
- interval
- timetz

### F.21.3. Authors

Teodor Sigaev <teodor@sigaev.ru>

## F.22. fuzzystmatch

The `fuzzystmatch` module provides several functions to determine similarities and distance between strings.

### Caution

At present, the `soundex`, `metaphone`, `dmetaphone`, and `dmetaphone_alt` functions do not work well with multibyte encodings (such as UTF-8).

This module is considered “trusted”, that is, it can be installed by non-superusers who have `CREATE` privilege on the current database.

### F.22.1. Soundex

The Soundex system is a method of matching similar-sounding names by converting them to the same code. It was initially used by the United States Census in 1880, 1900, and 1910. Note that Soundex is not very useful for non-English names.

The `fuzzystmatch` module provides two functions for working with Soundex codes:

```
soundex(text) returns text
difference(text, text) returns int
```

The `soundex` function converts a string to its Soundex code. The `difference` function converts two strings to their Soundex codes and then reports the number of matching code positions. Since Soundex codes have four characters, the result ranges from zero to four, with zero being no match and four being an exact match. (Thus, the function is misnamed — `similarity` would have been a better name.)

Here are some usage examples:

```
SELECT soundex('hello world!');

SELECT soundex('Anne'), soundex('Ann'), difference('Anne', 'Ann');
SELECT soundex('Anne'), soundex('Andrew'), difference('Anne', 'Andrew');
SELECT soundex('Anne'), soundex('Margaret'), difference('Anne', 'Margaret');

CREATE TABLE s (nm text);

INSERT INTO s VALUES ('john');
INSERT INTO s VALUES ('joan');
INSERT INTO s VALUES ('wobbly');
```

```
INSERT INTO s VALUES ('jack');
```

```
SELECT * FROM s WHERE soundex(nm) = soundex('john');
```

```
SELECT * FROM s WHERE difference(s.nm, 'john') > 2;
```

## F.22.2. Levenshtein

This function calculates the Levenshtein distance between two strings:

```
levenshtein(text source, text target, int ins_cost, int del_cost, int sub_cost) returns  
int
```

```
levenshtein(text source, text target) returns int
```

```
levenshtein_less_equal(text source, text target, int ins_cost, int del_cost, int  
sub_cost, int max_d) returns int
```

```
levenshtein_less_equal(text source, text target, int max_d) returns int
```

Both `source` and `target` can be any non-null string, with a maximum of 255 characters. The cost parameters specify how much to charge for a character insertion, deletion, or substitution, respectively. You can omit the cost parameters, as in the second version of the function; in that case they all default to 1.

`levenshtein_less_equal` is an accelerated version of the Levenshtein function for use when only small distances are of interest. If the actual distance is less than or equal to `max_d`, then `levenshtein_less_equal` returns the correct distance; otherwise it returns some value greater than `max_d`. If `max_d` is negative then the behavior is the same as `levenshtein`.

Examples:

```
test=# SELECT levenshtein('GUMBO', 'GAMBOL');  
levenshtein
```

```
-----  
2  
(1 row)
```

```
test=# SELECT levenshtein('GUMBO', 'GAMBOL', 2, 1, 1);  
levenshtein
```

```
-----  
3  
(1 row)
```

```
test=# SELECT levenshtein_less_equal('extensive', 'exhaustive', 2);  
levenshtein_less_equal
```

```
-----  
3  
(1 row)
```

```
test=# SELECT levenshtein_less_equal('extensive', 'exhaustive', 4);  
levenshtein_less_equal
```

```
-----  
4  
(1 row)
```

## F.22.3. Metaphone

Metaphone, like Soundex, is based on the idea of constructing a representative code for an input string. Two strings are then deemed similar if they have the same codes.

This function calculates the metaphone code of an input string:

```
metaphone(text source, int max_output_length) returns text
```

source has to be a non-null string with a maximum of 255 characters. `max_output_length` sets the maximum length of the output metaphone code; if longer, the output is truncated to this length.

Example:

```
test=# SELECT metaphone('GUMBO', 4);
 metaphone
-----
      KM
(1 row)
```

## F.22.4. Double Metaphone

The Double Metaphone system computes two “sounds like” strings for a given input string — a “primary” and an “alternate”. In most cases they are the same, but for non-English names especially they can be a bit different, depending on pronunciation. These functions compute the primary and alternate codes:

```
dmetaphone(text source) returns text
dmetaphone_alt(text source) returns text
```

There is no length limit on the input strings.

Example:

```
test=# SELECT dmetaphone('gumbo');
 dmetaphone
-----
      KMP
(1 row)
```

## F.23. hstore

This module implements the `hstore` data type for storing sets of key/value pairs within a single Postgres Pro value. This can be useful in various scenarios, such as rows with many attributes that are rarely examined, or semi-structured data. Keys and values are simply text strings.

This module is considered “trusted”, that is, it can be installed by non-superusers who have `CREATE` privilege on the current database.

### F.23.1. hstore External Representation

The text representation of an `hstore`, used for input and output, includes zero or more `key => value` pairs separated by commas. Some examples:

```
k => v
foo => bar, baz => whatever
"1-a" => "anything at all"
```

The order of the pairs is not significant (and may not be reproduced on output). Whitespace between pairs or around the `=>` sign is ignored. Double-quote keys and values that include whitespace, commas, `=`s or `>`s. To include a double quote or a backslash in a key or value, escape it with a backslash.

Each key in an `hstore` is unique. If you declare an `hstore` with duplicate keys, only one will be stored in the `hstore` and there is no guarantee as to which will be kept:

```
SELECT 'a=>1,a=>2'::hstore;
 hstore
-----
"a"=>"1"
```

A value (but not a key) can be an SQL `NULL`. For example:

```
key => NULL
```

The `NULL` keyword is case-insensitive. Double-quote the `NULL` to treat it as the ordinary string “NULL”.

## Note

Keep in mind that the `hstore` text format, when used for input, applies *before* any required quoting or escaping. If you are passing an `hstore` literal via a parameter, then no additional processing is needed. But if you're passing it as a quoted literal constant, then any single-quote characters and (depending on the setting of the `standard_conforming_strings` configuration parameter) backslash characters need to be escaped correctly. See [Section 4.1.2.1](#) for more on the handling of string constants.

On output, double quotes always surround keys and values, even when it's not strictly necessary.

## F.23.2. hstore Operators and Functions

The operators provided by the `hstore` module are shown in [Table F.17](#), the functions in [Table F.18](#).

**Table F.17. hstore Operators**

| Operator                                        | Description                                                        | Example(s)                                                                                                        |
|-------------------------------------------------|--------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------|
| <code>hstore -&gt; text -&gt; text</code>       | Returns value associated with given key, or NULL if not present.   | <code>'a=&gt;x, b=&gt;y'::hstore -&gt; 'a' -&gt; x</code>                                                         |
| <code>hstore -&gt; text[] -&gt; text[]</code>   | Returns values associated with given keys, or NULL if not present. | <code>'a=&gt;x, b=&gt;y, c=&gt;z'::hstore -&gt; ARRAY['c','a'] -&gt; {"z","x"}</code>                             |
| <code>hstore    hstore -&gt; hstore</code>      | Concatenates two hstores.                                          | <code>'a=&gt;b, c=&gt;d'::hstore    'c=&gt;x, d=&gt;q'::hstore -&gt; "a"=&gt;"b", "c"=&gt;"x", "d"=&gt;"q"</code> |
| <code>hstore ? text -&gt; boolean</code>        | Does hstore contain key?                                           | <code>'a=&gt;1'::hstore ? 'a' -&gt; t</code>                                                                      |
| <code>hstore ?&amp; text[] -&gt; boolean</code> | Does hstore contain all the specified keys?                        | <code>'a=&gt;1,b=&gt;2'::hstore ?&amp; ARRAY['a','b'] -&gt; t</code>                                              |
| <code>hstore ?  text[] -&gt; boolean</code>     | Does hstore contain any of the specified keys?                     | <code>'a=&gt;1,b=&gt;2'::hstore ?  ARRAY['b','c'] -&gt; t</code>                                                  |
| <code>hstore @&gt; hstore -&gt; boolean</code>  | Does left operand contain right?                                   | <code>'a=&gt;b, b=&gt;1, c=&gt;NULL'::hstore @&gt; 'b=&gt;1' -&gt; t</code>                                       |
| <code>hstore &lt;@ hstore -&gt; boolean</code>  | Is left operand contained in right?                                | <code>'a=&gt;c'::hstore &lt;@ 'a=&gt;b, b=&gt;1, c=&gt;NULL' -&gt; f</code>                                       |
| <code>hstore - text -&gt; hstore</code>         | Deletes key from left operand.                                     | <code>'a=&gt;1, b=&gt;2, c=&gt;3'::hstore - 'b'::text -&gt; "a"=&gt;"1", "c"=&gt;"3"</code>                       |
| <code>hstore - text[] -&gt; hstore</code>       | Deletes keys from left operand.                                    |                                                                                                                   |

| <b>Operator</b>                   | <b>Description</b>                                                                                     | <b>Example(s)</b>                                                      |
|-----------------------------------|--------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------|
|                                   |                                                                                                        | 'a=>1, b=>2, c=>3'::hstore - ARRAY['a','b'] → "c"=>"3"                 |
| hstore - hstore → hstore          | Deletes pairs from left operand that match pairs in the right operand.                                 | 'a=>1, b=>2, c=>3'::hstore - 'a=>4, b=>2'::hstore → "a"=>"1", "c"=>"3" |
| anyelement #= hstore → anyelement | Replaces fields in the left operand (which must be a composite type) with matching values from hstore. | ROW(1,3) #= 'f1=>11'::hstore → (11,3)                                  |
| %% hstore → text[]                | Converts hstore to an array of alternating keys and values.                                            | %% 'a=>foo, b=>bar'::hstore → {a,foo,b,bar}                            |
| %# hstore → text[]                | Converts hstore to a two-dimensional key/value array.                                                  | %# 'a=>foo, b=>bar'::hstore → {{a,foo},{b,bar}}                        |

**Table F.18. hstore Functions**

| <b>Function</b>                    | <b>Description</b>                                                                                     | <b>Example(s)</b>                                                                                              |
|------------------------------------|--------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------|
| hstore ( record ) → hstore         | Constructs an hstore from a record or row.                                                             | hstore(ROW(1,2)) → "f1"=>"1", "f2"=>"2"                                                                        |
| hstore ( text[] ) → hstore         | Constructs an hstore from an array, which may be either a key/value array, or a two-dimensional array. | hstore(ARRAY['a','1','b','2']) → "a"=>"1", "b"=>"2"<br>hstore(ARRAY[['c','3'],['d','4']]) → "c"=>"3", "d"=>"4" |
| hstore ( text[], text[] ) → hstore | Constructs an hstore from separate key and value arrays.                                               | hstore(ARRAY['a','b'], ARRAY['1','2']) → "a"=>"1", "b"=>"2"                                                    |
| hstore ( text, text ) → hstore     | Makes a single-item hstore.                                                                            | hstore('a', 'b') → "a"=>"b"                                                                                    |
| akeys ( hstore ) → text[]          | Extracts an hstore's keys as an array.                                                                 | akeys('a=>1,b=>2') → {a,b}                                                                                     |
| skeys ( hstore ) → setof text      | Extracts an hstore's keys as a set.                                                                    | skeys('a=>1,b=>2') →<br><br>a<br>b                                                                             |
| avals ( hstore ) → text[]          | Extracts an hstore's values as an array.                                                               |                                                                                                                |

Additional Supplied Modules  
and Extensions Shipped in  
postgrespro-ent-14-contrib

| Function                                                       | Description                                                                                                                                                  | Example(s)                                                                                                                                                                                                                   |

|                                                                |                                                                                                                                                              | <code>avals('a=&gt;1,b=&gt;2') → {1,2}</code>                                                                                                                                                                                |
| <code>svals(hstore) → setof text</code>                        | Extracts an hstore's values as a set.                                                                                                                        | <code>svals('a=&gt;1,b=&gt;2') →</code><br><br>1<br>2                                                                                                                                                                        |
| <code>hstore_to_array(hstore) → text[]</code>                  | Extracts an hstore's keys and values as an array of alternating keys and values.                                                                             | <code>hstore_to_array('a=&gt;1,b=&gt;2') → {a,1,b,2}</code>                                                                                                                                                                  |
| <code>hstore_to_matrix(hstore) → text[]</code>                 | Extracts an hstore's keys and values as a two-dimensional array.                                                                                             | <code>hstore_to_matrix('a=&gt;1,b=&gt;2') → {{a,1},{b,2}}</code>                                                                                                                                                             |
| <code>hstore_to_json(hstore) → json</code>                     | Converts an hstore to a json value, converting all non-null values to JSON strings. This function is used implicitly when an hstore value is cast to json.   | <code>hstore_to_json('"a key"=&gt;1, b=&gt;t, c=&gt;null, d=&gt;12345, e=&gt;012345, f=&gt;1.234, g=&gt;2.345e+4') → {"a key": "1", "b": "t", "c": null, "d": "12345", "e": "012345", "f": "1.234", "g": "2.345e+4"}</code>  |
| <code>hstore_to_jsonb(hstore) → jsonb</code>                   | Converts an hstore to a jsonb value, converting all non-null values to JSON strings. This function is used implicitly when an hstore value is cast to jsonb. | <code>hstore_to_jsonb('"a key"=&gt;1, b=&gt;t, c=&gt;null, d=&gt;12345, e=&gt;012345, f=&gt;1.234, g=&gt;2.345e+4') → {"a key": "1", "b": "t", "c": null, "d": "12345", "e": "012345", "f": "1.234", "g": "2.345e+4"}</code> |
| <code>hstore_to_json_loose(hstore) → json</code>               | Converts an hstore to a json value, but attempts to distinguish numerical and Boolean values so they are unquoted in the JSON.                               | <code>hstore_to_json_loose('"a key"=&gt;1, b=&gt;t, c=&gt;null, d=&gt;12345, e=&gt;012345, f=&gt;1.234, g=&gt;2.345e+4') → {"a key": 1, "b": true, "c": null, "d": 12345, "e": "012345", "f": 1.234, "g": 2.345e+4}</code>   |
| <code>hstore_to_jsonb_loose(hstore) → jsonb</code>             | Converts an hstore to a jsonb value, but attempts to distinguish numerical and Boolean values so they are unquoted in the JSON.                              | <code>hstore_to_jsonb_loose('"a key"=&gt;1, b=&gt;t, c=&gt;null, d=&gt;12345, e=&gt;012345, f=&gt;1.234, g=&gt;2.345e+4') → {"a key": 1, "b": true, "c": null, "d": 12345, "e": "012345", "f": 1.234, "g": 2.345e+4}</code>  |
| <code>slice(hstore, text[]) → hstore</code>                    | Extracts a subset of an hstore containing only the specified keys.                                                                                           | <code>slice('a=&gt;1,b=&gt;2,c=&gt;3'::hstore, ARRAY['b','c','x']) → "b"=&gt;"2", "c"=&gt;"3"</code>                                                                                                                         |
| <code>each(hstore) → setof record(key text, value text)</code> | Extracts an hstore's keys and values as a set of records.                                                                                                    | <code>select * from each('a=&gt;1,b=&gt;2') →</code><br><br>key   value<br>-----+-----                                                                                                                                       |

| Function                                                         | Description                                                                                                          | Example(s)                                                                      |
|------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------|
|                                                                  |                                                                                                                      | <pre> a      1 b      2 </pre>                                                  |
| <code>exist ( hstore, text ) → boolean</code>                    | Does <code>hstore</code> contain key?                                                                                | <code>exist('a=&gt;1', 'a') → t</code>                                          |
| <code>defined ( hstore, text ) → boolean</code>                  | Does <code>hstore</code> contain a non-NULL value for key?                                                           | <code>defined('a=&gt;NULL', 'a') → f</code>                                     |
| <code>delete ( hstore, text ) → hstore</code>                    | Deletes pair with matching key.                                                                                      | <code>delete('a=&gt;1,b=&gt;2', 'b') → "a"=&gt;"1"</code>                       |
| <code>delete ( hstore, text[] ) → hstore</code>                  | Deletes pairs with matching keys.                                                                                    | <code>delete('a=&gt;1,b=&gt;2,c=&gt;3', ARRAY['a','b']) → "c"=&gt;"3"</code>    |
| <code>delete ( hstore, hstore ) → hstore</code>                  | Deletes pairs matching those in the second argument.                                                                 | <code>delete('a=&gt;1,b=&gt;2', 'a=&gt;4,b=&gt;2'::hstore) → "a"=&gt;"1"</code> |
| <code>populate_record ( anyelement, hstore ) → anyelement</code> | Replaces fields in the left operand (which must be a composite type) with matching values from <code>hstore</code> . | <code>populate_record(ROW(1,2), 'f1=&gt;42'::hstore) → (42,2)</code>            |

In addition to these operators and functions, values of the `hstore` type can be subscripted, allowing them to act like associative arrays. Only a single subscript of type `text` can be specified; it is interpreted as a key and the corresponding value is fetched or stored. For example,

```

CREATE TABLE mytable (h hstore);
INSERT INTO mytable VALUES ('a=>b, c=>d');
SELECT h['a'] FROM mytable;

```

```

h
---
b
(1 row)

```

```

UPDATE mytable SET h['c'] = 'new';
SELECT h FROM mytable;

```

```

h
-----
"a"=>"b", "c"=>"new"
(1 row)

```

A subscripted fetch returns `NULL` if the subscript is `NULL` or that key does not exist in the `hstore`. (Thus, a subscripted fetch is not greatly different from the `->` operator.) A subscripted update fails if the subscript is `NULL`; otherwise, it replaces the value for that key, adding an entry to the `hstore` if the key does not already exist.

### F.23.3. Indexes

`hstore` has GiST and GIN index support for the `@>`, `?`, `?&` and `?|` operators. For example:

```

CREATE INDEX hidx ON testhstore USING GIST (h);

```

```
CREATE INDEX hidx ON testhstore USING GIN (h);
```

`gist_hstore_ops` GiST opclass approximates a set of key/value pairs as a bitmap signature. Its optional integer parameter `siglen` determines the signature length in bytes. The default length is 16 bytes. Valid values of signature length are between 1 and 2024 bytes. Longer signatures lead to a more precise search (scanning a smaller fraction of the index and fewer heap pages), at the cost of a larger index.

Example of creating such an index with a signature length of 32 bytes:

```
CREATE INDEX hidx ON testhstore USING GIST (h gist_hstore_ops(siglen=32));
```

`hstore` also supports `btree` or `hash` indexes for the `=` operator. This allows `hstore` columns to be declared `UNIQUE`, or to be used in `GROUP BY`, `ORDER BY` or `DISTINCT` expressions. The sort ordering for `hstore` values is not particularly useful, but these indexes may be useful for equivalence lookups. Create indexes for `=` comparisons as follows:

```
CREATE INDEX hidx ON testhstore USING BTREE (h);
```

```
CREATE INDEX hidx ON testhstore USING HASH (h);
```

## F.23.4. Examples

Add a key, or update an existing key with a new value:

```
UPDATE tab SET h['c'] = '3';
```

Another way to do the same thing is:

```
UPDATE tab SET h = h || hstore('c', '3');
```

If multiple keys are to be added or changed in one operation, the concatenation approach is more efficient than subscribing:

```
UPDATE tab SET h = h || hstore(array['q', 'w'], array['11', '12']);
```

Delete a key:

```
UPDATE tab SET h = delete(h, 'k1');
```

Convert a record to an `hstore`:

```
CREATE TABLE test (col1 integer, col2 text, col3 text);
INSERT INTO test VALUES (123, 'foo', 'bar');
```

```
SELECT hstore(t) FROM test AS t;
           hstore
```

```
-----
"col1"=>"123", "col2"=>"foo", "col3"=>"bar"
(1 row)
```

Convert an `hstore` to a predefined record type:

```
CREATE TABLE test (col1 integer, col2 text, col3 text);
```

```
SELECT * FROM populate_record(null::test,
                               '"col1"=>"456", "col2"=>"zzz"');
```

```
 col1 | col2 | col3
-----+-----+-----
  456 | zzz  |
(1 row)
```

Modify an existing record using the values from an `hstore`:

```
CREATE TABLE test (col1 integer, col2 text, col3 text);
INSERT INTO test VALUES (123, 'foo', 'bar');
```

```
SELECT (r).* FROM (SELECT t #= '"col3"=>"baz"' AS r FROM test t) s;
 col1 | col2 | col3
-----+-----+-----
  123 | foo  | baz
(1 row)
```

## F.23.5. Statistics

The `hstore` type, because of its intrinsic liberality, could contain a lot of different keys. Checking for valid keys is the task of the application. The following examples demonstrate several techniques for checking keys and obtaining statistics.

Simple example:

```
SELECT * FROM each('aaa=>bq, b=>NULL, ""=>1');
```

Using a table:

```
CREATE TABLE stat AS SELECT (each(h)).key, (each(h)).value FROM testhstore;
```

Online statistics:

```
SELECT key, count(*) FROM
  (SELECT (each(h)).key FROM testhstore) AS stat
GROUP BY key
ORDER BY count DESC, key;
```

| key    | count |
|--------|-------|
| line   | 883   |
| query  | 207   |
| pos    | 203   |
| node   | 202   |
| space  | 197   |
| status | 195   |
| public | 194   |
| title  | 190   |
| org    | 189   |
| .....  |       |

## F.23.6. Compatibility

As of PostgreSQL 9.0, `hstore` uses a different internal representation than previous versions. This presents no obstacle for dump/restore upgrades since the text representation (used in the dump) is unchanged.

In the event of a binary upgrade, upward compatibility is maintained by having the new code recognize old-format data. This will entail a slight performance penalty when processing data that has not yet been modified by the new code. It is possible to force an upgrade of all values in a table column by doing an `UPDATE` statement as follows:

```
UPDATE tablename SET hstorecol = hstorecol || '';
```

Another way to do it is:

```
ALTER TABLE tablename ALTER hstorecol TYPE hstore USING hstorecol || '';
```

The `ALTER TABLE` method requires an `ACCESS EXCLUSIVE` lock on the table, but does not result in bloating the table with old row versions.

## F.23.7. Transforms

Additional extensions are available that implement transforms for the `hstore` type for the languages PL/Perl and PL/Python. The extensions for PL/Perl are called `hstore_plperl` and `hstore_plperlu`, for

trusted and untrusted PL/Perl. If you install these transforms and specify them when creating a function, `hstore` values are mapped to Perl hashes. The extensions for PL/Python are called `hstore_plpythonu`, `hstore_plpython2u`, and `hstore_plpython3u` (see [Section 48.1](#) for the PL/Python naming convention). If you use them, `hstore` values are mapped to Python dictionaries.

### Caution

It is strongly recommended that the transform extensions be installed in the same schema as `hstore`. Otherwise there are installation-time security hazards if a transform extension's schema contains objects defined by a hostile user.

## F.23.8. Authors

Oleg Bartunov <oleg@sai.msu.su>, Moscow, Moscow University, Russia

Additional enhancements by Andrew Gierth <andrew@tao11.riddles.org.uk>, United Kingdom

## F.24. Hunspell Dictionaries Modules

These modules provide Hunspell dictionaries for various languages. Upon installation of the module into database using `CREATE EXTENSION` command, text search dictionary and configuration objects in the public schema appear.

**Table F.19. Modules**

| Language         | Extension name              | Dictionary name               | Configuration name            |
|------------------|-----------------------------|-------------------------------|-------------------------------|
| American English | <code>hunspell_en_us</code> | <code>english_hunspell</code> | <code>english_hunspell</code> |
| Dutch            | <code>hunspell_nl_nl</code> | <code>dutch_hunspell</code>   | <code>dutch_hunspell</code>   |
| French           | <code>hunspell_fr</code>    | <code>french_hunspell</code>  | <code>french_hunspell</code>  |
| Russian          | <code>hunspell_ru_ru</code> | <code>russian_hunspell</code> | <code>russian_hunspell</code> |

### F.24.1. Examples

Text search objects will be created after installation of a dictionary module. We can test created configuration:

```
SELECT * FROM ts_debug('english_hunspell', 'abilities');
  alias | description | token | dictionaries |
  dictionary | lexemes
-----+-----+-----+-----
+-----+-----+
  asciiword | Word, all ASCII | abilities | {english_hunspell,english_stem} |
  english_hunspell | {ability}
(1 row)
```

Or you can create your own text search configuration. For example, with the created dictionaries and with the `Snowball` dictionary you can create mixed russian-english configuration:

```
CREATE TEXT SEARCH CONFIGURATION russian_en (
  COPY = simple
);

ALTER TEXT SEARCH CONFIGURATION russian_en
  ALTER MAPPING FOR asciiword, asciihword, hword_asciipart
  WITH english_hunspell, english_stem;
```

```
ALTER TEXT SEARCH CONFIGURATION russian_en
  ALTER MAPPING FOR word, hword, hword_part
  WITH russian_hunspell, russian_stem;
```

You can create mixed dictionaries only for languages with different alphabets. If languages have similar alphabets then Postgres Pro can not decide which dictionary should be used.

A text search configuration which is created with a dictionary module is ready to use. For example, in this text you can search some words:

```
SELECT to_tsvector('english_hunspell', 'The blue whale is the largest animal');
      to_tsvector
-----
'animal':7 'blue':2 'large':6 'whale':3
(1 row)
```

Search query might look like this:

```
SELECT to_tsvector('english_hunspell', 'The blue whale is the largest animal')
  @@ to_tsquery('english_hunspell', 'large & whale');
   ?column?
-----
t
(1 row)
```

With this configurations you can search a text using GIN or GIST indexes. For example, there is a table with GIN index:

```
CREATE TABLE table1 (t varchar);
INSERT INTO table1 VALUES ('The blue whale is the largest animal');
CREATE INDEX t_idx ON table1 USING GIN (to_tsvector('english_hunspell', "t"));
```

For this table you can execute the following query:

```
SELECT * FROM table1 where to_tsvector('english_hunspell', t)
  @@ to_tsquery('english_hunspell', 'blue & animal');
      t
-----
The blue whale is the largest animal
(1 row)
```

## F.25. in\_memory

The `in_memory` extension enables you to store data in Postgres Pro shared memory using in-memory tables implemented via foreign data wrappers (FDW).

### Note

This extension cannot be used together with prepared transactions or while built-in connection pooling is enabled.

In-memory tables are *index-organized* — table rows are stored in leaf pages of the B-tree index defined on the primary key for the table. This solution offers the following benefits:

- Fast random access on the primary key. This can result in significant performance benefits when working with data that requires a very high read and write access rate, especially on multi-core systems.
- Effective space usage. There is no primary key duplication as all data is stored directly in the index.

In-memory tables support transactions, including savepoints. However, the data in such tables is stored only while the server is running. Once the server is shut down, all in-memory data gets truncated. When using in-memory tables, you should also take into account the following restrictions:

- Persistence, WAL, and data replication are currently not supported for in-memory tables.
- Secondary indexes are not supported.
- Isolation levels are supported up to `REPEATABLE READ`. `SERIALIZABLE` isolation level is not supported. `REPEATABLE READ` level is used instead.
- In-memory tables do not support TOAST or any other mechanism for storing big tuples. Since the in-memory page size is 1 kB, and the B-tree index requires at least three tuples in a page, the maximum row length is limited to 304 bytes.
- When a row is deleted from an in-memory table, the corresponding data page is not freed. See [Section F.25.2.3](#) for details.

## F.25.1. Installation and Setup

To enable in-memory tables for your cluster:

1. Make sure that the [postgres\\_fdw](#) module is enabled.
2. Add the `in_memory` value to the `shared_preload_libraries` variable in the `postgresql.conf` file:  

```
shared_preload_libraries = 'in_memory'
```
3. Create the `in_memory` extension using the following statement:

```
CREATE EXTENSION in_memory;
```

As a result, the `in_memory` foreign server is created, and a separate shared memory pool is allocated for in-memory tables, with pre-created pages for storing in-memory data. For in-memory tables, smaller locality is required for effective memory access, as compared to hard drives or SSD, so in-memory page size is 1 kB only. Once the extension is created, you can start using in-memory tables as explained in [Section F.25.2](#).

### Tip

If required, you can increase the memory size allocated for in-memory tables. For details, see [Section F.25.2.6](#).

## F.25.2. Usage

### F.25.2.1. Creating In-Memory Tables

To add an in-memory table to your database, create a foreign table on the `in_memory` server, using the regular [CREATE FOREIGN TABLE](#) syntax. By default, a unique B-tree index is built upon the first column, in the ascending order. If required, you can use the `INDICES` option in the `OPTIONS` clause to define a different B-tree index structure, as follows:

```
OPTIONS ( INDICES '[ UNIQUE ] {column [ COLLATE collation ] [ASC | DESC] } [, ... ]' )
```

where *column* is the column to include into the B-tree index, and *collation* is the name of the collation to use for this column. You can specify up to eight arbitrary columns separated by commas, with sorting options defined for each of these columns (`COLLATE`, `ASC/DESC`). The `UNIQUE` declares the created index unique, reiterating the default behavior.
